In 1886, the Enos Electric Railway tested and demonstrated the first suspended monorail at the Daft Electric Company in Greenville, New Jersey. The newspapers gave the Greenville demonstration considerable publicity, but Enos Electric Railway didn't build a major monorail system. The monorail itself featured a light, open steelwork design instead of the traditional massive wooden beams, a design that may have influenced civil engineer Eugen Langen of Cologne, Germany, since the Enos Monorail closely resembles the Wuppertal Schwebebahn in Germany. In fact, Langen deserves widespread recognition for his Schwebebahn, or suspension railway, which has operated successfully and profitably along the Wupper River since 1901.

Frenchman Charles Lartigue designed the original steam-powered monorail which ran for 9 miles between Listowel and Ballybunion, Ireland, from 1888 to 1924. The only monorail of its kind to enjoy commercial success, it carried passengers, livestock, and freight along a rail supported on A-shaped trestles, and during its lifetime it provided curiosity and amusement.

Monorail technology continued to advance and improve in the 20th and 21st centuries. Inventor Louis Brennan patented his monorail car balanced with gyroscopes in 1903, and on November 10, 1909, he demonstrated to the press that even with passengers grouped on one side of the car, the two onboard gyroscopes were strong enough to keep the car level. Despite successfully demonstrating his car several times to scientists, engineers, and military officers, Brennan never had the satisfaction of seeing his monorail used for transportation, because investors and officials feared that the gyroscopes might fail.

In 1910, William H. Boyes and two assistants, whose names have been lost to history founded the Seattle–Tacoma Monorail Company to provide high-speed rail service between Puget Sound cities in Washington State. He built a test track with wooden rails in 1911 at the estimated cost of around \$3,000 per mile, but he couldn't develop it further because of the lack of financial backing.

In 1924, the Sierra Salt Corporation built one of the last Lartigue-style monorails to carry magnesium salts from the mine in Crystal Hills across the rugged terrain of the Saline Valley to the Trona railroad in California. The monorail line worked

successfully until modern technology made extracting magnesium easy and the mining company went out of business in 1926.

In 1947, a French consortium of 25 companies including Michelin and Renault, and a design team headed by Lucien Chadenson produced a new monorail technology. Impressed by the Paris Metro Route 11 and the Bennie Railplane experimental line operating near Glasgow, Scotland, designer Chadenson decided to combine the two ideas and he produced a suspended monorail with bogies protected from the weather inside a steel or concrete box beam above the train. Calling his design the Safege Monorail, Chadenson operated the test track south of Paris for many years. The Siemens Company in Germany developed a smaller system similar to the Safege Monorail and Aerorail of Dallas, Texas, and Sky Train of Palm Harbor, Florida, also operate steel wheel versions of Safege.

By the 1950s Alweg monorails, including the the systems in Germany and at Disneyland and Disney World, had captured the attention of a segment of the public. In 1952, Swedish industrialist Dr. Axel Lennart Wenner-Gren built the first monorail test track in Germany after World War II and tested it on the Fuhlingen track with a system design geared toward a high-speed, city-to-city rail system. Although the Alweg system impressed people with its stellar speed and banking capabilities, it did not settle into its niche until 1957, when Alweg unveiled and tested its first modified full-scale monorail at the Fuhlingen track. The successful test caught the attention of a Walt Disney representative, and in 1959, Disneyland opened its Alweg monorail. As technology progressed, so did versions of the Disneyland Alweg monorail, and in 1971, Walt Disney World in Florida built a large dual-rail system, which on a typical day carries more than 150,000 visitors around the resort and theme park.

While many Americans thought of monorails simply as theme park rides, Japan included the monorail in its extensive campaign to improve its transportation system. In 1957, the first Japanese monorail system appeared at the Ueno Zoo in Tokyo, when the Ueno line replicated Wuppertal's system using unique parts, including rubber tires. Japan adopted the Alweg and Safege monorail systems and eventually built more transit monorails than any other country in the world, including a

full-sized Alweg monorail for the Tokyo Disneyland Resort in the 1990s.

Monorail systems also cornered a portion of the 1960s transportation market, including the 1962 Seattle World's Fair, with a dual-rail Alweg line which still operates today. To promote their Safege licensed monorail, the American Machine and Foundry Company (AMF) installed and operated a one-station I-Beam monorail with dual-rail systems looping around the amusement area for the 1964–65 New York World's Fair. Although AMF never sold or built any Safege monorails, the system they installed at the New York World's Fair drew more enthusiastic attention to monorail systems.

In 1964, the Tokyo–Haneda Monorail, the first major system to incorporate the Alweg design and use switches for direction reversal, opened, and it continues to operate safely and profitably into the 21st century. Since the mid 1950s, Japan has used monorails to carry commuters in large cities like Tokyo and Osaka, and Osaka has the longest monorail line in the world. Osaka's 17-mile-long monorail connects the airport to 17 other stations.

São Paulo

Although São Paulo, Brazil, is the largest city in South America with more than 11 million residents, it has only about 44 miles of subway lines that carry an average of 3.6 million passengers a day. City officials are expanding several transportation modes, but they are focusing especially on monorails as the cheapest and fastest way to relieve transportation congestion. Line 17-Gold is a planned 11-mile monorail system that will connect Congonhas International Airport to the metro rail network in São Paulo, beginning at Jabaquara terminus station on Line 1-Blue and ending at Morumbi station of Line 4-yellow and passing through the southern and southwestern part of the city. The arch-shaped route will link four metro lines and three bus corridors and feature 18 stations.

Companhia do Metropolitano de São Paulo (CMSP), the line operator, contracted with a consortium made up of Scomi Engineering of Malaysia, Andrade Gutierrez, CR Almeida, Engenharia de obras and Montagens e Projectos Especiais for the \$862-million project in June 2011 to build the monorail system, which is expected to take three and one-half years to complete, with a completion date set for 2016. One of the three monorail lines

The Sydney, Australia, straddle-beam monorail, shown here in 2012, operated from 1988 to 2013. It ran in only a single 2.2-mile loop and suffered from low ridership.

being planned for São Paulo, Line 17, is expected to serve 252,000 passengers a day with trains traveling at a headway of 200 seconds.

According to the terms of the contract, Malaysia-based Scomi Engineering will furnish the rolling stock, the vehicle management systems, switch design and system integration, assurance testing and commissioning. Scomi Engineering will supply 24 car train sets of its Sutra monorail trains, which have the capacity to transport 400 passengers in each direction. Sutra Monorail features a straddle-type car with a single-shell body made of composite materials. Each cab has six windows and four bi-parting, external sliding doors; the cab interior is spacious and allows passengers to move around freely. The car is equipped with a 40-kilowatt, roof-mounted air-conditioned unit

and it moves on a single beam on an elevated corridor, occupying minimal space. The Sutra Monorail uses an electric motor, runs on a lower power supply, and is designed to travel at a top speed of approximately 56 miles an hour. The Sutra is designed with the capability of installing an automatic train protection system and automatic train operation equipment; its vehicle management system provides system supervisory, control, monitoring, and diagnostic functions.

Metro São Paulo plans to complete three other monorail systems by 2015. Line 2-Green extension opened in 2012 with 17 stations. Line 16-Silver is expected to be 5 miles long with 10 stations. Work on Silver began in 2012 and is scheduled to be finished by 2015. Canadian train and plane maker Bombardier, Inc., was one of a consortium of companies winning a contract worth \$1.44 billion to build the first new 14.9-mile section. The monorail, with 17 stations and 54 seven-car trains, will connect several low-income neighborhoods to existing subway service. Planners estimate that the monorail line, scheduled to open in 2014, will draw approximately 40,000 commuters per hour from all directions.

Costs of Building a Monorail System

According to the Monorail Society, an organization that gathers data and promotes use of monorail technology, the most popular question that people ask about monorail is how much they cost to build; according to the Monorail Society, there is no simple answer to the question. The costs of monorail systems range from the \$120 million infrastructure and operating costs of the Osaka, Japan, monorail system opened in 1990 to the \$1.44 billion contract that Bombardier, Inc., signed to build a monorail system in São Paulo, which is scheduled to open in 2014.

A variety of variables and circumstances influence the price of building a monorail system. The total length of the system is important, and a general rule of thumb can be the longer the system is, the lower the cost. Topography or the lay of the land is an important cost factor as is whether the land is flat or hilly. The number of roads and rivers to cross and the amount of land needing to be purchased or easements secured are also important. The location and access to the land and relocating or locating utilities also affect the cost of building

a monorail. Factors like access for construction equipment, and traffic and other impediments to construction, as well as relocating water mains, and power and telephone lines, influence monorail costs. The size and number of passenger vehicles and the number of stations required, as well as special structures like tunnels, bridges, overpasses and urban structures, add to the cost of monorail construction. Environmental mitigation such as the restoration and protection of wildlife is also a cost factor.

The Monorail Association contends that despite the cost of building it, a monorail system has one of the best chances of all transit modes of turning a profit, and it publishes an alphabetical list of the approximate costs figures of various monorail systems on its Web site. The Monorail Association also advises that the list is in no way complete and readers can obtain more accurate cost figures from the manufacturer or a monorail savvy consultant.

Advantages and Disadvantages

Historically, monorails have had mixed reviews, with one faction hailing them as a model for future public transportation systems and critics relegating them to theme park attractions too slow and small to serve as urban transit systems.

Now large cities in emerging economies looking for quick, low-cost solutions to mobility bottlenecks are scrutinizing the advantages of elevated single-track trains. Besides Chongqing, China, and São Paulo, Brazil, monorail systems are being constructed in Mumbai, India; Riyadh, Saudi Arabia; Daegu, South Korea; and at least a dozen other places around the world.

Despite successful monorail construction, Kim Pedersen, head of the Monorail Society in 2013, believes that the perception that monorail is unproven in a mass transit setting has persisted. Concerns about evacuating stranded passengers from overhead trains and the idea that elevated monorails spoil urban landscapes have also hindered the growth of monorails.

Monorail makers like Bombardier and Hitachi Ltd. state that modern monorails are quieter and vibrate less than earlier models. Some of the new trains are lighter, which means that elevated structures aren't as bulky and allow more natural light than do older designs. Bombardier also reports that the São Paulo system will feature evacuation walks between tracks,

and Eran Gartner, president of the transportation division of Bombardier in 2013, which also builds other train systems, says subways can cost roughly 50 percent more than monorails to build depending on their location.

Opponents of monorail systems argue that most people won't forsake their cars to ride monorail systems, but some people will decide to take the monorail instead of driving for at least a few of their trips, especially those that involve driving in congested traffic and costly downtown parking. Other monorail opponents argue that monorail systems costs too much, but light rail or subway costs much more, while bus rapid transit costs less but is slower and has more impact on traffic. Critics question whether monorail systems can ever be suitable for urban mass transit. In 2013, George Haikais headed the Institute for Rational Urban Mobility, a New York-based nonprofit organization focused on transportation reform. He believed that the efficiency of monorail was still an open-ended question and "the evidence is that it is not a substitute for conventional railroad at least when it comes to carrying large numbers of passengers."

Motor Carrier Act of 1980

Trucking companies account for more than half of the shipping value and tonnage transported throughout the United States each year, making the motor carriage a leading mode of freight transportation across the country. The industry became federally regulated under the Motor Carrier Act of 1935 and remained subject to government-imposed restrictions until the Motor Carrier Act of 1980 eased controls and ushered in the prevailing era of deregulation.

In the deregulated environment, motor carrier companies have become more innovative and efficient in their operations and more focused on delivering service quality at a reasonable cost in order to succeed in the increasingly competitive market.

Historical Perspective

Motor carriers in the United States enjoyed broad independence prior to 1935. The freedoms led to a glut of providers and generated an oversupply of transportation services that stifled pricing and profits. In efforts to remain competitive in the years during and following the Great Depression, many trucking operators resorted to dangerous and sometimes unscrupulous activities, ranging from foregoing equipment maintenance and requiring drivers to work extended hours to abandoning shipments midway through a job and even racketeering.

Congress stepped in to provide regulatory structure with the Motor Carrier Act of 1935. The legislation gave the Interstate Commerce Commission authority to issue and enforce regulations designed to protect industry participants and the shipping public from corrupt practices. The regulatory system succeeded in reducing bad behaviors, but it also gave rise to such stringent entry requirements that near-monopolies were created and prices for motor carriage soared.

The Motor Carrier Act of 1935 required truckers to have a certificate of public convenience and necessity before they could operate as a motor carrier. Obtaining the required certificate was extremely difficult, because it placed a heavy burden of proof on the trucker. For example, established truckers had to submit extensive documentation demonstrating that they operated as a motor carrier prior to 1935. New companies seeking to enter the industry were required to establish, among

other things, that their service was consistent with the public interest and did not unnecessarily duplicate established motor carrier services. In addition, the Interstate Commerce Commission determined that existing motor carriers should be given authority over new ones, making it hard to expand or create new services. Regulatory restrictions on driving through other truckers' routes muddled things further, because some carriers were forced to choose alternate routes that added hundreds of miles to the journey just to avoid another trucker's route.

Motor carriers were required under the 1935 act to file their rates with the Interstate Commerce Commission 30 days prior to the intended effective date. Once filed, competitors were permitted to review each other's rates and contest them. Moreover, regulatory price controls prevented carriers from raising rates, leading them to pass tariffs and other cost-of-business increases directly onto customers. Under the administration of President Jimmy Carter, Congress passed the Motor Carrier Act of 1980 in an effort to strike a better balance within the industry and get pricing under control. While it did not completely deregulate the motor carrier industry, the act did ease barriers to entry and price restrictions. The increased flexibility was intended to have an anti-inflationary effect on the costs of doing business, both within the motor carriage industry and for companies and consumers using freight trucking services.

Specifically, the act was designed to promote fair competition and reasonable rates for the movement of goods via motor carriers, facilitate diversity in quality and price options to meet market demands and consumer requirements, and enable motor carrier operators to earn sufficient profits, lure capital, and maintain fair wages and working conditions.

Impact of Deregulation

The Motor Carrier Act of 1980 changed the regulatory procedures for obtaining trucking licenses, utilizing routes, publishing rates, and setting prices. The less restrictive operating environment led to an increase in competition, with the number of trucking companies in the United States increasing dramatically following implementation of the act. In particular, there was a significant increase in the number of small-truckload operators, most of whom could not have gotten operating certificates required under the earlier regulation because of

the process and costs involved. Following the 1980 act, these smaller carriers were able to obtain their own operating certificates, enabling them to offer services as independent providers within interstate markets. The number of licensed motor carriers more than doubled from approximately 18,000 to around 45,000 in the first decade after deregulation.

Another form of entry in the postderegulation motor carrier industry was from previously certified carriers that had been restricted by route-use rules. After 1980, they were able to enter new geographic regions more easily. Truckers could also avoid costly and lengthy detours, and expand, specialize, and better coordinate their networks to achieve economies of scale and scope. The new environment also enabled carriers to lower operating costs. For example, labor and time expenses, as well as fuel costs that used to be required to accommodate shipments via circuitous routes, were suddenly available for other uses.

With increased flexibility in both pricing and service arrangements provided under the Motor Carrier Act, U.S. motor carriers were able to respond more fluidly and naturally to evolving market conditions. Among the favorable consequences were generalized price reductions and increased efficiencies tied to inventories, movement of goods, and service levels. On the negative side, trucking workers overall were paid less in salary and wages after deregulation. In the regulated environment, a majority of truckers belonged to workers' unions that ensured they were paid some 50 percent more than workers in comparable occupations. After 1980, the number of unionized workers dropped significantly percentagewise as more independent and low-cost smaller operators without union representation took advantage of the less restrictive entry requirements and joined the playing field.

The increase in number and breadth of motor carrier providers served to substantially heighten competition throughout the industry. Diminished regulatory requirements and removal of antitrust issues prompted many carriers for the first time to look beyond price as the main differentiating factor. In large part, motor carriers across the United States expanded to include technology advances, more innovative tactics, and customized collaborations in order to remain profitable and competitive. The focus turned toward selling service quality in the form of swift service completion, reliable service

guarantees, appropriate equipment availability, and improved information technology capabilities.

Related Legislation

Since the passage of the Motor Carrier Act of 1980, other acts of legislation pertaining to trucking transport have been passed to address issues such as rate protection and transportation safety.

The Negotiated Rates Act of 1993 offered shippers options and protections regarding undercharge agreements on interstate shipments. An undercharge occurs when a carrier agrees in good faith to a discounted shipping rate. The act also prohibited off-invoice discounting in which suppliers would obtain a discounted transportation rate from their carriers while the receiver would be billed for the full rate.

The Trucking Industry Regulatory Reform Act of 1994 eliminated the need to file individually determined rates with the Interstate Commerce Commission, and established a 180-day limitation for contesting freight invoices. The following year, however, the Interstate Commerce Commission Termination Act of 1995 abolished the commission and transferred some of its authorities, such as licensing and economic regulation, to the Federal Highway Administration and the Surface Transportation Board. Following the passing of the Motor Carrier Safety Improvement Act of 1999, the Federal Motor Carrier Safety Administration was established as of January 1, 2000. The agency currently holds primary regulatory responsibility for the operations of motor carrier brokers and freight forwarders.

The Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) of 2005 reduced the licensing and bonding requirements for third-party surface transportation brokers and freight forwarders.

Motor Fuel Taxes

A major component of road and highway funding in the United States comes from motor fuel tax revenues. Motor fuel taxes are the largest source of highway revenues at the federal level and have been one of the primary approaches used by the states to finance their highways and roads. Motor fuel taxes are levied as a fixed amount per gallon. Since the mid-1990s, the federal gasoline tax has been set at 18.4 cents per gallon (cpg) and the federal diesel tax at 24.4 cpg; these taxes make up the bulk of federal funds in the Highway Trust Fund. However, there are several challenges associated with the fuel tax in its current structure, and alternatives, such as the vehicle miles traveled (VMT) fee and a tax based on equivalent standard axle loads (ESAL), are being considered by policymakers and researchers.

Economic Principles

The theory behind the motor fuel tax is that the people and businesses using the roads should pay for their construction and upkeep through an equation that relates to their usage. This would, for example, account for things such as the number of miles traveled, the wear imposed by the vehicle (which is highly correlated to vehicle weight), additional congestion caused by the vehicle's operation, and pollution emitted by the vehicle. Implementing a user fee system would also directly correlate to all these factors, but it would be quite costly and could have significant potential drawbacks. An alternative to this direct charge is to tax a complementary good—in this case, gasoline.

Fuel consumption is related to road use in two important ways. First, the more a person drives, the

more gasoline is consumed. As a result, more tax revenue is paid by individuals who travel greater distances or rely more heavily on roads for transportation. Second, heavier vehicles tend to use more gasoline per mile of travel than lighter vehicles. Heavier vehicles, which impose more of a physical burden on the existing roads, will then pay more in taxes compared to lighter vehicles.

Historically, the gas tax has been considered somewhat equitable. More recently, the widening variation in vehicle fuel efficiency and the development of alternative fuels have broken the clear link between fuel usage and the costs a given vehicle would impose on the road system, thus weakening the assumed equity of the motor fuel tax.

There have been concerns that lower income groups might bear a disproportionate burden of gasoline cost and its associated taxes. However, research in the United States has found mixed evidence that the fuel tax is regressive. In addition, fuel taxes could account for the environmental costs attributed to various vehicle users and, by discouraging fuel purchases and driving, help reduce air pollution, carbon dioxide emissions, traffic congestion, traffic accidents, and oil dependency.

Motor Fuel Tax Structure and Rates

In the United States, the states took the lead in introducing and implementing the motor fuel tax. Oregon was the first state to introduce the motor fuel tax in 1919, and within 10 years, every state had followed suit and enacted its own fuel tax. At the federal level, the fuel tax was first levied in 1932. Each state, as well as the federal government, sets its own tax rates for different fuels (for example, gasoline, diesel, gasohol, and other special fuels). The motor fuel tax is a manufacturer's excise tax; therefore, the first entity to refine, distribute, or wholesale gasoline (and other motor fuels) pays the tax on the fuel. Often, this tax-paying entity is a distributor, importer, refiner, retail manufacturer, licensed dealer, supplier, or wholesale distributor, who then incorporates the tax into the wholesale price and passes it through to the end user.

The traditional fuel tax is structured as a fixed-rate tax, where the tax rate is statutorily defined and can only be changed by an act of legislation. For most states with traditional motor-fuel-tax rate structures, the tax rate remains fixed at X cents per gallon until legislation is passed changing

the tax rate to Y cents per gallon. The frequency of legislation, along with the size of the changes to the tax rates, dictates how well the motor fuel tax responds to changes such as increasing fuel efficiency or inflation. It is often politically difficult for legislators to raise the tax rate. As such, rate changes are often far and few between.

Most states and the federal government have the traditional fixed-rate structure. Several states, however, have a variable or indexed tax-rate structure where the tax rate adjusts automatically with changing rates of inflation or changing fuel economy. Since 1970, 16 states and the District of Columbia have employed some form of the variable-rate fuel tax structure. As of 2010, seven states had variable-rate fuel taxes.

When the federal gasoline tax was introduced in 1932, the tax rate was 1 cpg. As shown in Table 1, the federal tax rate has been continuously authorized but at levels that have varied across the years. Currently, the federal tax rate on gasoline is 18.4 cpg and the federal tax rate on diesel is 24.4 cpg.

Table 1 Federal tax on gasoline

Tax Rate (cents per gallon)	Applicable Period
1.0	June 21, 1932 to June 16, 1933
1.5	June 17, 1933 to December 31, 1933
1.0	January 1, 1934 to June 30, 1940
1.5	July 1, 1940 to October 31, 1951
2.0	November 1, 1951 to June 30, 1956
3.0	July 1, 1956 to September 30, 1959
4.0	October 1, 1959 to March 31, 1983
9.0	April 1, 1983 to December 31, 1986
9.1	January 1, 1987 to August 31, 1990
9.0	September 1, 1990 to November 30, 1990
14.1	December 1, 1990 to September 30, 1993
18.4	October 1, 1993 to December 31, 1995
18.3	January 1, 1996 to September 30, 1997
18.4	October 1, 1997 to September 30, 2016

Source: Bickley, James M. "The Federal Excise Tax on Gasoline and the Highway Trust Fund: A Short History." Congressional Research Service (September 7, 2012).

Significant variations in tax rates can also be seen across the states. For example, while the average tax rate is approximately 21 cpg, the tax rates for gasoline and diesel are the lowest in Georgia (7.5 cpg for each) and highest in Washington (gasoline tax rate of 37.5 cpg) and Connecticut (diesel tax rate of 46.2 cpg).

Even when the federal and state taxes are combined, the fuel tax in the United States is the lowest among industrial countries. In fact, gasoline and diesel are more heavily taxed in other developed, emerging, and developing countries. The combined tax of approximately 40 cpg (federal 18.4 cpg combined with state average of 21.4 cpg) in the United States is only a fraction of the United Kingdom's gasoline tax of approximately \$2.89 per gallon.

According to data from the Organisation for Economic Co-operation and Development (OECD), the United States has the lowest fuel tax compared to other member countries of the International Energy Agency (IEA). The U.S. tax on unleaded gasoline comprised only 16.5 percent of the unleaded gasoline price paid by consumers in 2010. In comparison, the Netherlands and United Kingdom had the highest fuel tax as a percentage of the unleaded gasoline price (63.4 percent and 62.3 percent, respectively). Canada's fuel tax component was 32.2 percent and Australia's was 37.2 percent. As shown in Table 2, in December 2012, the United States had the lowest average end-use tax on gasoline and

diesel compared to France, Germany, Italy, Spain, United Kingdom, Japan, and Canada.

Challenges and Alternatives to the Fuel Tax

Over the past 50 years, the ability of fuel tax revenues to finance transportation has declined. This is the result of two factors. First, inflation has diminished the purchasing power of the fuel tax, because, absent statutory changes to the tax rate, the traditional fixed per-gallon fuel tax does not respond to inflationary pressures. While the nominal gas tax has continued to increase, the real tax rates have declined.

Second, improvements in vehicle fuel efficiency have resulted in less gasoline consumption per mile driven, which decreases fuel tax revenue even though the actual cost drivers impose on the roads through their usage is not decreased by the increased fuel efficiency. Because of this, users are paying less per mile driven today than they were years ago, assuming a constant real gas-tax rate. Improvements in vehicle fuel efficiency, coupled with the real decline in tax rates, has led to concerns over the continued viability and sustainability of fuel taxes as a source of transportation funding.

A simple solution to the fuel-tax problem could be to replace the traditional, fixed-rate structure with a variable-rate or indexed tax instead. The primary advantage of this variable structure is that it automates adjustments to the tax rate to maintain long-term real revenue, while at the same time avoiding the political battles and uncertainty that accompany tax legislation. The variable-rate structure, if indexed to inflation and fuel efficiency, would address the two key challenges of inflation and improving fuel efficiency. However, another major problem with the fuel tax is that it does not tax the distance travelled. An alternative to the fuel tax would be a user charge based on the distance traveled, instead of on the fuel consumed to travel the distance. Several states have experimented with fees based on the amount of travel undertaken, the time of day the road usage occurs, the type of vehicle, and the type of road being used. This fee, called the vehicle-miles traveled (VMT) fee, is a much better approximation of a user fee than the current fuel tax. However, a fixed VMT fee structure that is not indexed to some measure of inflation would suffer the same fate as the traditional fixed-rate motor-fuel tax when it comes to maintaining purchasing power.

Table 2 Average end-use tax per gallon of fuel (in \$ equivalents), as of December 2012

IEA Country	Gasoline	Diesel
France	4.139	2.067
Germany	4.512	2.335
Italy	5.093	3.041
Spain	3.449	1.824
United Kingdom	4.894	3.544
Japan	2.839	1.745
Canada	1.507	1.190
United States	0.420	0.485

Source: International Energy Agency. "End-Use Petroleum Product Prices and Average Crude Oil Import Costs, December 2012." <http://www.iea.org/stats/surveys/Prices/2012/MEMDEC12.XLS> (Accessed May 2013).

Another distance-based alternative would involve taxing trucks in proportion to the damage they inflict on roads. Pavement damage is a function of vehicle weight per axle, and can be defined in terms of equivalent standard axle loads (ESAL) causing the same damage. An ESAL-miles tax or fee would be proportional to the damage caused and the maintenance needed to fix the damage. An ESAL-miles tax or fee would have the added advantage of shifting some freight shipments to rail and barge, and reducing the need for new highway construction on some congested routes. It would also incentivize use of trucks with lower loads per axle or trucks with more axles, decreasing the damage to highways.

are less expensive to purchase, require less fuel, are easier to maneuver in congested traffic, and more convenient to park, they have become the staple motor vehicle in many developing countries in southern and eastern Asia. The four largest motorcycle markets in the world are China, India, Indonesia, and Vietnam. In the United States, there are approximately 11 million motorcycles, and the estimated number of Americans who ride motorcycles at least once a year is 25 million.

Motorcycles are primarily used as leisure vehicles by the American population; roughly 80 percent of the miles put on a motorcycle are from recreational trips, and 20 percent for commuting. Motorcycle registrations in the United States are increasing as people choose them to reduce gasoline consumption and urban congestion. While only 9 percent of the total U.S. adult population owns a motorcycle, they are 35 times more likely to experience a fatal accident on the road than automobile drivers. Head injuries are the leading cause of death in motorcycle crashes.

In spite of increasing motorcycle ownership in the United States, motorcycle riders are perceived in popular consciousness as rebels, criminals, and outsiders. From state to state, there is also a wide variety of definitions for categories of motorcycle. For these reasons, not all states require a distinct type of license or test for each variety of motorcycle. Some types of motorcycle are not subject to the same insurance or registration requirements as other motor vehicles. Along with the increasing rate of motorcycle accidents in the United States, these factors have led some people to call for a ban on some or all types of motorcycles. Meanwhile, motorcycle enthusiasts are lobbying the motorcycle producers for more safety features, as well as for state and federal governments to require safety training.

History of Motorcycle Use

Gottlieb Daimler and Wilhelm Maybach invented the first internal-combustion, gasoline-fueled motorcycle, called the Petroleum Reitwagen, in Bad Cannstatt, Germany, in 1885. While the Germans were the pioneers of motorcycle production, the Americans soon took the lead. In 1906, after many trials and errors, William S. Harley and Arthur Davidson established their first motorcycle factory in Milwaukee, Wisconsin. Police departments served as their first customer base,

Motorcycle Safety

There are approximately 200 million motorcycles in use around the world today. This count includes motorcycles, motor scooters, mopeds, and other similar motorized bicycles. Because motorcycles

and motorcycle racing among civilians became a popular pastime.

The U.S. military, perhaps, did the most to boost Harley-Davidson's influence on the motorcycle market and to further development of motorcycles and similar vehicles around the world. In 1916, General John "Blackjack" Pershing placed the first formal order with Harley-Davidson for motorcycles to use during the United States–Mexican border conflict. In 1917, the U.S. military demanded motorcycles from Harley-Davidson and Indian, another American motorcycle company, during World War I. When U.S. Corporal Roy Holtz was the first American to enter Germany on a Harley one day after the Armistice, the Harley-Davidson motorcycle became a symbol of American freedom and democracy. During World War II, Harley-Davidson supplied the United States and its allies with motorcycles. Their popularity among servicemen inspired Harley-Davidson to publish *The Enthusiast*, a magazine for motorcycle fans. The U.S. military continued to employ Harley-Davidson motorcycles in Japan, Korea, and Vietnam, as well as more recently in Iraq and Afghanistan. The growing worldwide popularity of motorcycles spurred manufacturing in Asian countries. Honda, Kawasaki, Suzuki, and Yamaha are among the Asian brands now being sold in the United States.

Over the years, military veterans and supporters purchased motorcycles from Harley-Davidson for civilian use. Motorcycle clubs began to form around mechanics' garages; while some groups came together for the shared joy of riding or racing, others combined motorcycle riding with criminal activities. Motorcycle riders are also perceived as people who valorize or flaunt risk. Gay pride parades often start with "Dykes on Bikes," motorcycles ridden by members from the lesbian motorcycle club with 22 chapters across the United States.

In contrast to the daredevil stereotype, safe motorcycle operation is promoted by national organizations such as the American Motorcyclist Association (AMA), which encourages safety, advocates for motorcyclists' interests, and sanctions races and events.

Motorcycle Safety Precautions

To prevent accidents, motorcyclists use "personal protective equipment" (PPE), also known as

A member of the U.S. Air Force works on some cornering exercises on a high-powered sport motorcycle at Ford Island, Hawai'i, during a military sport bike rider course that offered specialized training for military sport bike riders, June 2008.

"motorcycle gear." PPE provides improved visibility for the motorcyclist and other drivers, abrasion resistance, impact protection, and weather protection. In many countries, certain articles of PPE are required, and motorcycle manufacturers and governments recommend their use. Motorcycle gear includes a helmet, gloves, jackets, long pants with special protection for the knees and hips, boots, goggles or helmet visor, ear plugs, and vests in highly visible, reflective material. A full face helmet is recommended; the National Highway Traffic Administration assures motorcyclists that it does not interfere with vision or hearing.

U.S. military service members are required to wear a helmet, gloves, long-sleeved shirts, and over-the-ankle footwear or certified motorcycle boots when driving motorcycles. A motorcycle jacket with padding is also recommended

to reduce trunk and arm injuries; such a jacket is mandatory for German motorcyclists. These policies have been adopted into some state laws regarding civilian motorcycle operation but not nationwide. Most motorcycle riders take precautions to avoid windburn and flying debris during their rides by wearing leather jackets, long pants, helmets, boots, and bandannas, but riders of smaller, lighter motorbikes and scooters often ride without as much protective gear.

Motorcycles themselves include various safety features. New motorcycles must include headlights that turn on once the engine is started, crash bars to protect a rider's legs and engine from injury during a rollover or collision, and an antilock braking system that makes it easier and safer to stop the motorcycle. Yamaha and Suzuki are currently testing airbag devices on motorcycles.

Motorcycle Safety Training Programs

People interested in riding a motorcycle should contact their state department of motor vehicles (DMV) for information on licensing. The potential rider will often have to meet an age requirement, pass written and vision tests, and pay a permit application fee in order to acquire their learner's permit. While active-duty military and veterans might have received motorcycle safety training in the service, most states will not accept this training in place of passing state-approved tests.

Each state allows different time frames, ranging from 20 days to at least six months, to prepare for the road test in order to acquire a motorcycle license. Potential drivers must provide a "street legal," registered motorcycle for their road test. After passing the road test, some states will add a "motorcycle endorsement" on the new rider's driver license, if they have one, or print a separate license with photo identification.

The Motorcycle Safety Foundation (MSF) is a national not-for-profit organization sponsored by BMW, Harley-Davidson, Honda, Kawasaki, Suzuki, Yamaha, and other motorcycle producers. Established in 1974, MSD developed the Rider Education and Training System (RETS) and promotes continual safety education for riders and trainers known as "RiderCoaches." More than 2,700 so-called RiderCourse sites exist throughout the United States to provide basic RETS. MSF also lobbies the government for safer riding

environments, motorcycle safety research, and state training and licensing programs.

Approximately 400,000 motorcyclists enroll in MSF courses each year, and some states will waive their on-bike riding skills test and/or their written test if a rider has an RETS Course Completion Card. The MSF *Motorcycle Operator Manual* is the model for many state DMV reference handbooks for motorcycle applicants; they also provide a "Sharing the Roadway" booklet for nonmotorcyclists to help prevent collisions. Forty-five states have a state motorcycle safety coordinator. Most operate through a state-approved motorcycle safety program, a highway safety office, a driving school, or a DMV. The safety coordinator can tell potential riders whether or not RETS is available or recognized in their state and how to apply for their program.

Since the occupation of Iraq, the U.S. Army has noted a dramatic increase in motorcycle-related injuries, hospitalizations, and deaths among service members, mirroring this phenomenon in the civilian world. Researchers found that young men, Marines, people on combat duty, and those with no education past high school were most at risk for accidents.

Nearly half of motorcycle fatalities involve a rider under the influence of alcohol or drugs. Automobile-centric motor vehicle laws do not always specify that driving a motorcycle under the influence is also illegal. As the motorcycle accident rate remains so high, it is crucial that any motorcycle education program stresses the importance of driving sober and well rested.

Motorcycles

The motorcycle mystique evokes feelings of power, speed, and freedom of the open road in people, whether or not they are cyclists themselves. Motorcycles evolved from simple, steam-powered bicycles to streamlined, powerful machines that have existed nearly as long as automobiles. Motorcyclists have developed a mystique and psychology of their own to go along with their machines.

Even in its early years, both athletes and spectators saw the motorcycle's potential for transportation as well as racing and sport, and they demanded more powerful, versatile, and comfortable machines. By the first decade of the 1900s, engineers for American motor cycle designers like Indian and Harley-Davidson experimented with twin cylinder engines that became standard on most motorcycles. By the start of World War I in 1914, the motorcycle had evolved from an experimental primitive machine to dependable, speedy, and inexpensive transportation.

By the end of World War I, motorized tanks and airplanes were common equipment and during the 1920s BMW, Moto Guzzi, and Triumph began producing their first motorcycles with great success especially in Europe. Despite competition from the automobile, American motorcycle sales remained

relatively stable throughout the 1920s. The Depression of the 1930s forced several motorcycle companies out of business while others barely survived. After the Second World War, the motorcycle manufacturing industry enjoyed a boom in sales that lasted through the 1950s. Europeans wanted cheap transportation because of austere wartime economic conditions, and the more economically sound American consumers snapped up dirt bikes and larger capacity motorcycles, escalating motorcycle sales to peak highs for the decade of the 1950s. With European manufacturers dominating the market, only Harley-Davidson survived as an American manufacturer of motorcycles.

Motorcycle technology also improved during the 1940s and 1950s, including advances in suspension, dual seats and sidecars, and push button ignition, but aging motorcycle design and engineers encountered growing competition from the automobile industry. In the 1960s, Japanese companies increasingly challenged the Western motorcycle market with their sophisticated Hondas, Suzukis, and Yamahas. Initially, Japanese motorcycles made only small inroads in the Western market until consumers learned how to operate the Japanese machines that featured superior technology and strong performance. Soon Japanese motorcycles outmatched contemporary European and American manufacturers and by 1970, Honda had introduced its pioneering four-cylinder, four-stroke engine that introduced a generation of enhanced motorcycles. The growing sport of motorcycle racing also promoted motorcycle manufacturers to improve the two-wheeler motorcycle with more powerful engines and more reliable braking. During the 1980s and 1990s, manufacturers built more powerful and technologically sophisticated motorcycles and the motorcycle grew in importance as a symbol of speed and the magic and freedom of the road.

To 21st-century enthusiasts, motorcycles are much more than transportation; they symbolize status and freedom. Modern motorcycles have evolved from the early days of the two wheeler to computerized technology and custom bikes for different purposes. Cyclists can choose sport bikes, off-road bikes, scooters, and super and customized bikes. Future motorcycle designs such as new versions of leg protectors and air bags ensure continuing technological designs, but safely will remain an important consideration in motorcycle design.

Members of the Rolling Thunder advocacy group on the Memorial Bridge in Washington, D.C., May 2009. This annual ride brings attention to the issue of prisoners of war/missing in action (POW/MIA) service members from the Vietnam War and other wars. The rally and ride, which culminates in a stop at the Vietnam Veterans' Memorial, included over 500,000 motorcycles in 2013.

The Motorcycle Mystique

Technology has enhanced the safety features and low gas mileage of motorcycles. The pleasure of racing on the open road has contributed to the motorcycle mystique, as have the proximity of the motorcyclist and surrounding environment and the skill and knowledge required to ride the razor's edge between danger and safety. British motorcyclist and historian T. E. Lawrence who logged at least 100,000 miles of his life on motorcycles and eventually died on a motorcycle, summarized the speed mystique of motorcycles for most riders when he said, "...I could write for hours on the lustfulness of moving swiftly." All of these factors have contributed to the motorcycle image, but social not mechanical traits dominate the motorcycle mystique.

Motorcycles and their riders have a complex social history, with the modern motorcycle image beginning in the 1930s and continuing with motorcycle clubs after World War II and their impact on media and culture. In the late 1930s, Linda Dugeau of Providence, Rhode Island, loved motorcycles and

she thought the other women who owned and treasure their motorcycles should meet and share their enthusiasm. She wrote to motorcycle dealers, other motorcycle riders, and anyone else she thought might know women motorcycle riders, and she finally produced a list of women motorcycle enthusiasts. In 1940, Linda Dugeau founded the Motor Maid organization with 51 charter members, and the American Motorcycle Association issued Charter #509 to the Club in 1941. The Motor Maids have maintained their identity and governing structure since then, making a valid claim to being the oldest established motorcycle club in the world.

In his motorcycle history, *Born to Be Wild*, writer Paul Garson tells the story of American GIs returning home from World War II and creating motorcycle clubs as a way of coping with the transition into civilian life. Although the reasons for the clubs were complex and psychological, including recreating the camaraderie of the service, motorcycle clubs became popular and weekend gatherings of hundreds of riders commonplace.

Most motorcycle gatherings were peaceful, but during a large 1947 rally in Hollister, California, several motorcycle clubs erupted into violence. Local police arrested approximately 60 riders for mostly minor offenses, but they felt so outnumbered by the number of cyclists that they called the state highway patrol for assistance. Newspapers and other media soon dubbed the event “The Hollister Riot.” *The San Francisco Chronicle* called the incident an “outburst of terrorism,” claiming that 4,000 motorcyclists had captured the town, and *Life Magazine* staged photographs of beer and bikers. Although reports of biker behavior at Hollister were later found to be exaggerated, “the Hollister Riot” had already created the myth of the lawless, problem biker in the public imagination. Films like *The Wild One* in 1953, with Marlon Brando portraying the rebellious cyclist Johnny Strabler, symbolized the public perception of motorcycle culture and inspired generations of young motorcycle enthusiasts.

Different versions of the Hollister idea has been repeated through the decades after the 1940s as have differing versions of the founding of the Hells Angels motorcycle club, but the media reacted to motorcycle clubs in the same way. Newspapers, magazines, and radio and television stations nationwide tended to emphasize and exaggerate stories of lawless cyclists, ravished women, and outlaw culture. The 1950s fears of juvenile delinquency and the stormy culture seas of the 1960s expanded the motorcycle mystic in different directions and made cyclists even more controversial. Many people considered groups like the Hells Angels symbols of cultural deterioration while others like Sixties radicals and academics saw them as antiheroes. A resurgence of biker films in the 1960s and 1970s, including *The Wild Angels* (1966), *Cycle Savages* (1969), and the classic *Easy Rider* (1969), added to the myth of motorcyclists as modern cowboys, challenging the rigidity and conformity of American culture.

Yet, the contrasts between the image of the rebellion and even lawlessness of motorcycle riding are ironic. There are established standards of dress and behavior for motorcyclists. Black leather and helmets are classic styles for safety as well as image reasons. Motorcyclists may think they are free, but their machines are not free and they have to operate within a modern consumer economy to afford their motorcycle freedom.

Twenty-First-Century Motorcycles

Motorcyclists wave to each other on the road without social screenings or class connections and participate in important commemorations like the annual journey to the Vietnam Veterans’ Memorial. Motorcyclists in the 21st century ride into the heart of the true meaning and importance of motorcycling when they share the community and experiences that transcend nationality, gender, race, and the other dividers between human beings.

Moving Ahead for Progress in the 21st Century Act

The Moving Ahead for Progress in the 21st Century Act, or MAP-21, was passed by the U.S. Congress by wide majorities on June 29, 2012, and signed into law by President Barack Obama a week later. A surface transportation funding reauthorization bill, MAP-21 keeps federal spending about the same in the two years to which it applies but enacts reforms that the Congressional Budget Office estimates will

reduce the federal budget deficit by over \$15 billion by 2022.

MAP-21 was introduced in the House by John Mica (R-FL) as H.R. 4348 on April 16, 2012, and passed the House 293-127 on April 18. It passed the Senate by unanimous consent on April 24. After being reported by the joint conference committee on June 28, 2012, the final bill was agreed to by both the House (373-52) and the Senate (74-19) on June 29. Although the bill was introduced by a Republican, Republicans were the only ones to vote against the bill.

Overall, MAP-21 reduces transportation expenditures by consolidating the number of funding programs. It also calls for the development of a national freight policy and gives states and other recipients of federal transportation funding significantly more flexibility in how they spend that funding. A total of \$118 billion was authorized for surface transportation programs over 27 months, extending then-current federal funding through fiscal year 2014 and maintaining funding levels and gas tax revenue share of public transit at present levels. Long-term transportation financing was not addressed, and it will either be addressed in 2014 or Congress will again have to consider legislation to extend previous spending levels as a stopgap measure.

The consolidated transportation programs include four core programs: The Highway Safety Improvement Program, the Congestion Mitigation and Air Quality Program, the Surface Transportation Program, and the National Highway Performance Program. The Highway Safety Improvement Program is the same as under the previous act, the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy For Users (SAFETEA-LU), as is the Congestion Mitigation and Air Quality Program. The Surface Transportation Program, already extant, grew by absorbing several SAFETEA-LU programs. The new National Highway Performance Program was created by combining the Highway Bridge Program, Interstate Maintenance, and the National Highway System funding program.

MAP-21 followed the previous transportation funding bill SAFETEA-LU, which was signed into law on August 10, 2005, and expired on September 30, 2009. Though remembered largely for the \$200-million "Bridge to Nowhere" in Alaska, SAFETEA-LU was an important bipartisan transportation bill that went far beyond highway funding to

grant much-needed federal funding support to public transportation, bicycle programs, pedestrian programs, and other areas.

Criticisms

MAP-21 drew sharp criticism from many quarters, especially in contrast to the 2009 stimulus bill, which had called for widespread transportation infrastructure improvements and an increase in federal development of green jobs. Bicycle and pedestrian programs were merged into a Transportation Alternatives (TA) program with reduced funding, half of which is given to the states. The other half is disbursed to the metropolitan planning organizations (MPOs), created by the Federal-Aid Highway Act of 1962, of which there are now 342. Also within TA are road work, environmental mitigation, a recreational trails program, and the Safe Routes to School program, making it likely that an insignificant amount of the TA funds, already considerably reduced from the previous law, will go to bicycle programs.

Private sector funding and alternative funding mechanisms for highway and transit projects were increased. Electric vehicle charging and natural gas fueling stations were acknowledged as valid uses of funding from MAP-21's core programs. The deficit reductions created by MAP-21 are brought about without increasing transportation costs on the user end, making it 20 years since the federal gasoline tax was last increased, in 1993. Instead, revenue is created through an assortment of means, both inside and outside the transportation sector.

For instance, businesses that make roll-your-own-cigarette machines available to consumers were defined as tobacco manufacturers and required to pay a tax. Department of Transportation expenses were reduced by the repeal of an older requirement that the department reimburse the difference in cost for shipping foreign food aid on an American flag ship. Changes were also made to the way pension plans work, and certain federal employees were allowed to enter into a phased retirement in which they would draw part of their pension while continuing to work full-time.

Review Process

MAP-21 also streamlined the environmental review process, excluding many projects from the need for review and imposing a four-year deadline on

the process, less than half of the average time. The changes to the environmental review process were a significant victory for the conservative Republicans, who have traditionally opposed “big government” in the form of environmental regulations and review processes that they claim slow down the business of industry. The streamlining of the process reduced the role of the public in the planning of transportation projects by removing the public comment phase on water, air, and public-safety impacts. Public participation in the review process of activities with environmental impact has been a key element of federal environmental policy since President Richard Nixon signed the National Environmental Policy Act into law in 1969.

The streamlining of the review process, detailed under the Accelerated Decision Making portion of the bill, is given teeth by imposing a fine on federal agencies that do not meet the four-year deadline. The fine consists of a maximum of 7 percent of the agency’s fiscal year budget. Critics have pointed out that this creates a situation in which federal agencies seeking to avoid the fine are equally motivated to deny permits and to rush the environmental review process. Advocates point out that environmental reviews have in recent years ballooned into a lengthy and cumbersome process, and that four years should be sufficient time to address the public’s concerns and invite comment.

Projects exempted from the review process include all those with less than \$5 million in federal funding, or under \$30 million in funding when less than 15 percent of the funding is from federal sources. However, critics say there is no reason to think that funding levels are an adequate indicator of the presence, scope, or severity of potential environmental impact, or of the public’s interest in that environmental impact. Exemptions are also extended to “operational right of way” projects, which are transportation projects on property already used for transportation projects. This exemption has fewer critics. Categorical exemptions to environmental review apply to projects of infrastructure repair or new construction in response to a natural disaster.

Omissions

MAP-21 was also criticized for what it left out. For example, both the Keystone XL pipeline and coal ash regulations were put off to another time, and

potentially another Congress, just as this bill was itself something that had been put off for several years. The law also did not include \$1.4 billion for the Land and Water Conservation fund, which many hoped would be reauthorized so that lands in need of protection could be acquired.

A much-discussed provision to develop design standards to ensure that the transportation infrastructure could endure extreme weather was also removed from the final version of the bill. Perhaps worse, from an infrastructure-minded standpoint, the bill eliminated dedicated funding for transportation infrastructure repairs. Advocates of this elimination point out that this does not mean repair funding is not available; it is applied for in the same way that new projects apply for their funding. However, critics point out that dedicated funding is needed for repairs to bridges, highways, tunnels, and other transportation infrastructure throughout the country, especially when the frequency of extreme weather in the 21st century would seem to pose a particular danger to unrepaired infrastructure.

Other Provisions

Like many acts of Congress, MAP-21 included several riders unrelated to the bill’s main purpose. It extended federal student loan rates through June 2013, extended the Secure Rural School Acts by one year, authorized \$346 million for payments to heavily forested communities to compensate them for revenue lost by federal logging limitations, and reauthorized the national flood insurance program until 2017. In addition, \$2.4 billion was transferred from the Leaking Underground Storage Tank (LUST) fund to the Highway Trust fund, although the bill did not divert future LUST revenues as the Senate version of the bill proposed.

Another provision tied the spending of the Harbor Maintenance Trust Fund to its annual receipts. The act also called for an environmental impact study of Asian carp, motivated by concerns that the fish that has already infested the Mississippi River and its tributaries could enter the Great Lakes. Payments to states completing abandoned mine reclamation projects at the government’s request were capped at \$15 million annually. MAP-21 also included the The Resources and Ecosystems Sustainability, Tourist Opportunities and Revived Economies of the Gulf Coast States Act (RESTORE), which invests federal funding in Gulf

Coast restoration in the wake of the BP-Deepwater Horizon oil spill disaster. The act designates that 80 percent of the Clean Water Act penalties from BP's settlement of the 2010 disaster—which could reach \$21 billion—must be used for assistance to and the restoration of the communities, waters, coastlines and natural areas damaged by the spill.

Multiple Criteria Decision Making/Aiding

Up against myriad urban problems, diverse social and economic issues, and a limited financial budget, it might seem not just difficult but almost impossible to create a balance and identify the projects that would bring about the greatest benefits to society. Yet, planners all around the world strive to achieve that balance and prioritize their investments into the best projects. It is this balancing act that can be aptly termed "multiple criteria decision making" (MCDM), because it involves making decisions based on multiple criteria. While MCDM could relate to any field

or subject, in the context of transportation, it relates to how MCDM has been an effective tool in making public investment decisions such as project selection and prioritization.

In matters of public investment, budget constraints are always present, and it is vital to assess the contribution of a particular project to public welfare, as well as to choose a project with maximum welfare potential. However, there is a never a single decision maker behind project selection, and that decision is always made as a result of group discussions and compromises.

The decision-making process, in itself, is a significant factor in selecting a project, and recognition of this fact has led to the development of a framework of analysis for decision making where projects are analyzed against a set of criteria. This analysis framework can be called a decision-making support system (DSS). A DSS is usually a computer-based information system used to support decision-making activities in situations where it is not possible or desirable to have an automated system performing the entire decision process. A DSS also makes it easier to interpret multiple criteria, leading to faster and more efficient decision making. So, what are the different criteria and how are they assessed to make decisions?

Cost-Benefit Analysis

For a long time, cost-benefit analysis (CBA) has been the preferred tool to analyze the value of a project. The aim of using CBA is to be able to see if the benefits of a project are more than the costs involved, in which case a project can be called financially beneficial. CBA tries to monetize all benefits and costs of the project and finally arrives at a net present value (NPV) and an internal rate of return (IRR) upon which a project's financial feasibility is assessed. Initially used by private enterprises for private projects, CBA helps quantify the purely financial returns that a project is capable of delivering. Gradually, its use was extended to public projects, as well.

However, public bodies and public projects do not only have financial objectives to achieve. It is vital for the public projects also to attain maximum socioeconomic benefits. This means that certain parameters—such as time, safety, leisure, happiness, clean air, environmental preservation, and others—must also be measured. Unfortunately,

these parameters cannot be computed in the CBA model because they do not carry financial value. To analyze projects with such demands, social cost benefit analysis (SCBA) was carried out, until it was realized that SCBA could not entirely handle the assessment of projects that have impacts without direct monetary valuation.

Multiple Criteria Assessment

Thus, the need arose for a tool that enables assessment of various criteria that may or may not be assigned a financial value. This led to the development of the multiple criteria assessment (MCA) approach, where multiple criteria are measured in different units, not necessarily in monetary units, and aggregated using a function representing the decision maker's preference. MCA differs from CBA and SCBA in more than one way. While the primary aim of CBA is to identify the project with maximum financial benefits, MCA is used to determine the extent to which a project achieves a predetermined set of goals or objectives.

In the MCA process, all impacts of the project(s) are listed and weighted for their importance to the achievement of overall objectives. The project with highest score and best performance is then chosen for implementation. The objectives could be as defined under a policy statement or a development plan. For example, the objectives of a transport policy could be higher use of public transport, reduction in pollution levels, higher mobility in the region, and equitable distribution of goods and services. Various projects—such as a bus rapid transit (BRT) project, a light rail system, highway expansion, or constructing new roads—can all be assessed in MCA, and the project that achieves the objectives to greatest extent would be chosen for implementation.

MCA also takes into account the preferences of the decision maker(s) when all impacts of a project are weighted for their importance. The weights are assigned based on the decision maker(s)'s assessment of relative importance of the different criteria; hence, the results are not completely objective in nature. Due to the subjectivity in the weighting of parameters and criteria, there is always a possibility that the results could be manipulated and there is always some doubt about the robustness of its results.

Some experts also argue that MCA carries the danger of arbitrary assessments, and it might also

lead to double counting. MCA does not assess the worth of a project with regard to budget issues, although CBA provides specific results and numbers that are required for making budgetary decisions.

In view of all its pros and cons, it can be said that MCA is a good alternative only when projects involve important impacts that cannot be monetized, or if explicit attention needs to be paid to the perspectives of the decision makers. MCA might also be preferred when it is vital to consider the perspectives or preferences of involved stakeholders. More often than not, a decision on project selection does not depend on the wishes of one person but is a compromise among many different parties. For projects where all parameters cannot be given monetary value, MCA can identify all the relevant issues for several decision makers and rank the projects under various hypothetical sets of weights. That is, for n number of projects and w number of decision makers, there will be n times w options to choose among. The weights are not assigned based on the preferences of one decision maker, but all, and in the end, the group must choose one particular set or a combination of them.

Combined Platform

Despite the differences between CBA and MCA, both of these tools are increasingly seen as complementary rather than competitive. A middle path can be created wherein the advantages of both methods can be amalgamated to achieve the most comprehensive results. A pure MCA exercise could fail in almost all projects because the decision makers, due to political and other motivations, might never reveal their true objective preferences for certain criteria over others. Therefore, CBA and MCA can transition together into a DSS that presents all the facts before the decision makers, who can then make an informed decision and choose the alternative that is acceptable to the majority.

In that way, the DSS, like a CBA, can give the IRR and NPV and monetize the parameters that are used in SCBA. It also has an MCA module where a number of nonmonetary criteria are included and weighted by the users, with results derived to support the decision makers' assessment of all projects. Once all the parameters have been analyzed, the group of decision makers can then use all the information to discuss, argue, bargain, and finally choose the most agreeable option. Such a combined

platform can be called a DSS in the true sense that it aids in MCDM. When embedded into a geographic information system (GIS) platform, DSS becomes SDSS (spatial decision support system), which increases its transparency, repeatability, and user-friendliness.

An example of using DSS in MCDM is the EUNET project. In the 1990s, the European nations collectively wanted to improve their Trans-European Transport Network (TEN-T) to reduce regional disparities. However, there was uncertainty regarding the effects of various transport project types. The participating nations of European Commission were not sure which project would bring the most benefits. The EUNET project was initiated and funded by the European Commission with the aim of developing a comprehensive methodology to assess the impacts of transport initiatives, infrastructure investments, and regulatory and fiscal policies in the European Union region.

Under this program, a broad-based modeling system was developed to support policy decisions. The modeling system included an assessment framework that combined both CBA and MCA methods to value socioeconomic effects of a project. The model was demonstrated for the Trans-Pennine corridor in the United Kingdom and for long-distance freight movements in Finland. EUNET also provided an overview of current practice across European nations in appraising major

transport projects and deriving monetary values for impacts.

National Airspace System

The U.S. National Airspace System (NAS), administered by the Federal Aviation Administration (FAA), has responsibility for civil airspace over the United States and portions of the world's oceans. It is among the most complex, highly regulated global aviation systems. Flight safety is the primary goal of the NAS, followed by the secondary goals of expediency and efficiency. Air traffic congestion, terrorism and heightened security, economic downturns, aging infrastructure, and environmental concerns threaten the FAA's ongoing achievement of these goals. The FAA began development of the NAS redesign project, known as NextGen, to meet these concerns.

The need for safe and efficient air traffic control followed the explosive development of commercial aviation since World War II. The United States had become a global leader in terms of airspace use, as well as aircraft manufacturing and operation, by the end of the 20th century. Technological advances increasingly allowed pilots to fly relying solely on instruments in conditions of poor to no visibility, but air traffic control must maintain safe aircraft separation. Rising media coverage and victim counts in both ground and in-air aviation accidents also put public pressure on the federal government to better control its airspace.

The U.S. federal government created the NAS in response to these needs. The FAA publicizes its operational guidelines for the NAS in the *Federal Aviation Regulations/Aeronautical Information Manual* (FAR/AIM) series, among other print and Web-based publications.

The NAS also oversees the use of airport facilities, the Air Traffic Control (ATC) system, the designation of flight rules and procedures, and airspace system users. As of 2013, the NAS had 41,000 operational facilities under its control, including over 19,000 airports and 600 air traffic control facilities, according to FAA statistics. The NAS employs approximately 14,500 air traffic controllers, 4,500 aviation safety inspectors, and 5,800 technicians to serve an average of approximately 50,000 flights daily.

Objectives related to the overarching goals of safety, expediency, and efficiency include the prevention of flight conflicts and delays, the efficient use of flight paths, increased productivity and capacity, improved service, and the minimization of costs.

When events such as the 1981 air traffic controllers' strike or the 2013 implementation of mandatory federal budget cuts, known as sequestration, led to workforce reductions, flight delays and reductions resulted. From the viewpoint of NAS, capacity, cost, and convenience would have to be sacrificed rather than safety.

Flight Operations

Pilots operate under two categories of flight operations: Visual Flight Rules (VFR) or Instrument Flight Rules (IFR). Guidelines for operating under VFR or IFR are based on established meteorological criteria for visual flight conditions (VFC) or instrument flight conditions (IFC), such as visibility. These guidelines vary by airspace.

The establishment of VFR and IFR assists in the maintenance of safe separation between aircraft to avoid collisions. Separation distances are mandated by aircraft type, weather conditions, and the flight rules in effect. Pilots operating under VFR rely on visual identification of other aircraft and, when necessary, they perform maneuvers to avoid collisions, a process commonly known as see-and-avoid. Pilots operating under IFR rely on air traffic controllers for clearances, information on other aircraft in the vicinity, and, if necessary, any evasive maneuvers required.

IFR requires proper aircraft instrumentation and the pilot's passing of an instrument flight examination. When traveling through controlled airspace, pilots operating under IFR must also file a flight plan with the FAA, which provides relevant information about the aircraft, planned route, and passengers. Pilots operating under VFR also often file flight plans for safety reasons, even though they are not required to do so. Pilots are not allowed to operate under VFR if the established meteorological guidelines for that airspace are not met. Many pilots choose to operate under IFR for added safety, even if conditions are right for VFR.

Airspace Classifications

The FAA designates two main classifications within the national airspace: controlled and uncontrolled. Controlled airspace encompasses the area around heavily trafficked airports, along aircraft routes, and above 18,000 feet. The designation of controlled airspace allows for the safe and efficient movement of aircraft through the nation's busiest airspace and airports. IFR air traffic control services are available to any flight operating in controlled airspace, but not all flights must be controlled.

The FAA further classifies airspace into six classes: A (Alpha), B (Bravo), C (Charlie), D (Delta), E (Echo), and G (Golf), each of which is governed according to different flight rules, based on International Civil Aviation Organization airspace

classifications. The United States does not use the Class F airspace classification. Factors that designate airspace classification include location, size, services, and aircraft and pilot requirements. Each classification is governed by its own set of flight rules. A, B, C, D, and E are controlled. These classifications have been established with the primary goal of managing flights operating under VFR in controlled airspace, as ATC automatically manages flights operating under IFR.

Class G (Golf) accounts for uncontrolled airspace. "Special Use" and "Other" airspace classifications can include alert areas, military operations areas (MOA), prohibited areas, restricted areas, and warning areas. Airports operating within uncontrolled airspace may or may not have local operational air traffic control towers. The allowance of uncontrolled airspace frees air traffic controllers to concentrate on directing traffic within the often-congested controlled airspace.

Class A airspace encompasses all airspace from 18,000 feet up to and including 60,000 feet mean sea level (MSL) for the majority of the United States, with the exception of the Hawai'ian Islands. Class A is the most controlled of the six airspace classifications. Class B is heavily controlled airspace that encompasses the surface to 10,000 feet MSL around the U.S. airports that receive the most traffic. Class A and B are also respectively known as the positive control area and terminal control area.

Class C is individually designed controlled airspace at congested airports that receive lower traffic than their Class B counterparts. A typical Class C airspace usually extends 5 nautical miles in diameter with altitude up to 1,200 feet, and 10 nautical miles in diameter from 1,200 to 4,000 feet above ground level (AGL). All aircraft operating under VFR in Classes B, C, and D must maintain contact with ATC.

Class D is individually designed controlled airspace that usually extends 4 nautical miles in diameter, from the surface to 2,500 feet AGL. Class E, which encompasses most U.S. airspace, includes all airspace between the other four classes. Class G is uncontrolled airspace that extends from surface level to the Class E airspace above it, typically extending to a height of either 700 or 1,200 feet AGL. Aircraft may operate under VFR in Classes E and G airspace only under appropriate VFR conditions.

An Airbus A380 flies by the air traffic control tower at Wittman Regional Airport in Oshkosh, Wisconsin. While this airport is normally a less busy airport, when it hosts an annual experimental aircraft airshow it becomes the world's busiest airport by traffic movements. In the United States, controlled airspace encompasses the area around heavily trafficked airports, along aircraft routes, and above 18,000 feet. Airspace is also classified into categories that take into account the amount of traffic at an airport.

Air Traffic Control

The air traffic control system is a major component of the NAS, encompassing the airspace, facilities, equipment, and personnel; aeronautical charts and other information; and rules, regulations, and procedures necessary for the management of airspace use. ATC encompasses all aspects of flight, from departure, throughout the route, and to arrival. ATC provides assistance to aircraft, although the pilot and flight crew still bear ultimate responsibility for flight operations.

ATC maintains separation between aircraft, sequences arriving and departing flights, and allocates airspace and runways. ATC also provides flight planning, clearances, procedures, briefings, and in-flight navigation and advisories, while maintaining air-to-ground communication. Difficulties that can interfere with ATC performance include saturated air traffic levels, hazardous weather conditions,

individual facility outages, economic cutbacks, aging infrastructure, and personnel shortages.

Technological advances have allowed for communication between onboard flight management computer systems and ground-based ATC. ATC equipment and systems include VHF and UHF radios, Very High Frequency Omnidirectional Range (VOR) air navigation systems, nondirectional radio beacon Loran (Long Range Navigation) C, Controller Pilot Data Link Communications (CPDLC), Automatic Dependent Surveillance Broadcast (ADS-B), Global Positioning System (GPS), Instrument Landing (ILS) and Microwave Landing Systems (MLS), and ground-based radar systems. Both primary and secondary (beacon) ground-based radar systems are used for surveillance, with information transmitted from aircraft transponders. A separate surveillance system governs oceanic flights.

ATC facilities include Air Route Traffic Control Centers (ARTCC), Terminal Radar Approach Control (TRACON), and Flight Service Stations (FSS), as well as local airport air traffic control towers and ground controllers. This division of ATC services means that pilots communicate with a variety of air traffic controllers during the course of their flight. Pilots could receive preflight assistance or briefings and file flight plans through FSS, which also broadcast useful information such as weather conditions. FSS also could assist in locating lost aircraft or assisting aircraft in distress.

An ARTCC is responsible for air traffic operating under IFR within its regional sector of U.S. airspace while flights are en route between their departure and destination airports. Sectors are defined by geographical region, as well as horizontal and vertical limits. Each ARTCC has an air traffic controller and assistant controllers and its own assigned radio frequencies. Control of flights moving between regions is passed between the ARTCCs through a system of strict guidelines and procedures. ARTCCs accept flight plan amendments, issue clearances, maintain safe aircraft separation, issue traffic and weather advisories, issue collision-avoidance maneuvers, and assist distressed aircraft.

TRACON centers, located at major hub airports, coordinate with ARTCCs, assist arriving and departing flights, sequence and space aircraft, provide takeoff and landing clearances, and direct the flow of ground traffic around runways and gates. Terminal Radar Approach Cab (TRACAB) facilities often service smaller, lightly trafficked airports that do not house a TRACON center. ATC at terminal facilities employs both tower- and ground-based controllers. Controllers track aircraft visually or through radar and provide directions through radio communication or the use of signal lights.

Next Generation Air Transportation System

NAS capacity has been strained as a result of continued growth in air traffic since the late 20th century, which has led to congested runways and skies, travel delays, inefficiencies, and economic losses. Many current hub airports have already reached saturation levels, and they face additional projected passenger growth. Other issues—such as an aging infrastructure, increased fuel consumption and emissions, and rising fuel prices, as well as increased terrorism and heightened security after

the September 11, 2001, terrorist attacks—have also emerged as mounting concerns.

The FAA plans for the future through its mandated oversight of federal funding earmarked for airport expansion and redevelopment plans. The FAA has also responded to an increased volume of air traffic, which is projected to show continued growth, as well as other issues through a redesign of the NAS known as the Next Generation Air Transportation System (NextGen). NextGen is designed to cost-effectively optimize airspace use, improve performance, address terrorism and safety concerns, and mitigate environmental hazards, such as fuel use and emissions.

National Ambient Air Quality Standards

In 1948, bustling steel mills and coke plants lined the Monongahela River, from Donora, a mill town

of 14,000 people, north to Pittsburgh, 30 miles away. The Donora Zinc Works, a subsidiary of United States Steel Corporation, covered four of those miles and employed 6,500 people at the peak of its operations. Local people considered the noxious fog that drifted from the Zinc Works the price they paid for good jobs. Then, between October 26 and 31, 20 people choked to death and more than 7,000 were hospitalized or fell ill because of the health effects of severe air pollution.

The Clean Air Act and Amendments

State and federal health officials investigating the Donora air pollution produced the first dynamic federal and state laws aimed at controlling air pollution and the beginning of modern efforts to evaluate and combat health threats from air pollution. Several state laws were passed as well as the Clean Air Act of 1963, establishing funding for studying and cleaning up air pollution. The Clean Air Act passed in 1970 created the Environmental Protection Agency (EPA) and assigned it a primary role in enforcing the law. The EPA has been responsible for a variety of Clean Air Act programs to reduce nationwide pollution.

In 1990, Congress amended the Clean Air Act, giving the EPA more authority to implement and enforce National Ambient Air Quality Standards applying to outdoor air throughout the United States, with the goal of reducing air pollutant emissions and focusing on cost-effective approaches to reducing air pollution.

Role of the Environmental Protection Agency

Under the Clean Air Act, the EPA sets limits on certain air pollutants and how much of them can be present in the air anywhere in the United States, and these limits help ensure health and protection from air pollution for all Americans. The Clean Air Act also gives the EPA the authority to limit the amount of air pollutants coming from places like chemical plants, utilities, and steel mills, and it monitors the effectiveness of its regulations.

The Clean Air Act ensures the implementation of national standards and strategies to control air emission standards and the EPA cooperates with the states to integrate and enforce them. Individual states may pass stronger air pollution laws, but they are not allowed to have weaker pollution limits than the ones that the EPA has established.

Role of State and Local Government

It is logical for state and local air pollution agencies to take the initiative in carrying out the Clean Air Act, because state and local agencies have a special understanding of the local and state industries, geography, housing, and travel patterns, and they can develop customized solutions. Under the Clean Air Act, a state is required to develop a State Implementation Plan (SIP) outlining how it will control air pollution.

A SIP is a collection of the regulations, programs, and policies that the state will use to clean up polluted areas and the state must involve the public and industries through hearings and opportunities to comment on the development of the plan. State, local, and tribal governments also monitor air quality, inspect facilities, and enforce Clean Air Act regulations.

National Ambient Air Quality Standards

The Clean Air Act mandated the EPA to set National Ambient Air Quality Standards (NAAQS) for pollutants considered harmful to public health and the environment. For the purposes of the air quality program, ambient air is defined as the outdoor atmosphere, but not areas within fenced or restricted access boundaries of industrial facilities. The EPA is required to set National Ambient Air Quality Standards (40 CFR Part 50) for all criteria pollutants and it must review these standards once every five years to determine if they are appropriate or if new standards are required to protect public health.

The Clean Air Act identifies two kinds of standards: primary and secondary standards. Primary standards call for providing a margin of public health safety, including the well-being of “sensitive” populations such as people with asthma and other respiratory diseases, children, and elderly people. Secondary standards ensure public welfare measures, including protection against decreased visibility and damage to animals, crops, vegetation, and buildings.

An area that is found to have air quality as good as or better than the National Ambient Air Quality Standards for specified pollutants is called an attainment area, and one that does not meet the standards is considered a nonattainment area. An area can be in attainment for one pollutant and in nonattainment for others.

Six Principal Pollutants

The EPA has identified six principal air pollutants or criteria pollutants, based on a foundation of scientific studies conducted over a number of years. According to the EPA, the criteria pollutants are particulate matter, sulfur dioxide, carbon monoxide, nitrogen dioxide, ozone, and lead, and they are measured as either micrograms per cubic meter of air or parts per million by volume, parts per billion by volume, and micrograms per cubic meter of air.

Particle or particulate matter pollution includes microscopic liquids and solids that are found in vehicle exhaust, industrial emissions, and other sources. The EPA concludes that particle pollution requires both primary and secondary measures of micrograms per cubic meter of air, depending on daily and yearly concentrations.

Sulfur dioxide is a by-product of coal-fired power plants, industrial sources, residential heating, and motor vehicles. The EPA evaluates it as a primary pollutant, measuring it in parts per billion by volume and assessing its potential damage by its level of concentration.

Carbon monoxide is emitted from incomplete combustion of fuels from cars, buses, trucks, small engines, boilers, and industrial operations. The EPA considers it a pollutant requiring a primary margin for public health safety not exceeding a level of 9 parts per million by volume per eight hours.

Nitrogen oxides come from many sources, including diesel cars, trucks, buses, power plants, and industries; and nitrogen dioxide is mainly produced by internal combustion engines. It can decrease lung function and increase the risks of respiratory problems. The EPA considers nitrogen dioxide a pollutant covering both primary and secondary criteria, depending on its parts per billion by volume concentration and the amount of time it is present.

Ozone pollution, the main element of smog, forms in the air when volatile organic compounds and nitrogen oxides react with sunlight. The volatile organic compounds that form ozone come from vehicle and industrial exhaust, evaporated gasoline, solvents, paints, and other sources. The EPA assesses it both a primary and secondary pollutant measuring it in parts per million by volume and measuring its effects by concentration and duration.

Lead existed long before humans and poses an environmental and personal risk through

mediums including air, drinking water, food, deteriorating paint, and dust. Before scientists fully realized the harmful effects of lead, manufacturers used it in paint, gasoline, water pipes, and countless other products. High levels of lead can cause convulsions, coma, and death, and lower levels of lead can adversely affect the central nervous systems and impair mental and physical development in children. The EPA considers lead both a primary and secondary pollutant and assesses its concentration by measuring micrograms per cubic meter of air.

Ambient Air Quality Monitoring Program

State and local agencies implement the Environmental Protection Agency's Ambient Air Quality Monitoring Program, which consists of three primary categories of monitoring stations: State and Local Air Monitoring Stations (SLAMS), National Air Monitoring Stations (NAMS), and Special Purpose Monitoring Stations (SPMS), all of which measure the criteria pollutants.

The 1990 Amendments to the Clean Air Act required the implementation of a fourth monitoring station category called the Photochemical Assessment Monitoring Stations (PAMS), which measure ozone precursors, which are approximately 60 volatile hydrocarbons and carbonyl.

In the Ambient Air Monitoring Program, air quality samples are generally collected to determine compliance with or progress made toward meeting ambient air quality standards. Air quality samples can be used to activate emergency control procedures that prevent or ease air pollution or to observe pollution trends throughout the region, including nonurban areas. Air quality samples are collected to provide a database for research evaluation of effects, land use and transportation planning, development and evaluation of abatement strategies, and development and validation of diffusion models. Monitors are located in less than 1,000 of the 3,068 counties in the United States.

Attainment and Nonattainment

The attainment and nonattainment classifications are important components of the National Ambient Air Quality Monitoring Program. The best way to measure whether an area is in attainment is to install several ambient air monitors throughout the region or state to measure the concentrations

of pollutants in the ambient air. If the concentration of one or more criteria pollutants in a geographic area exceeds the regulated or threshold level of one or more of the National Ambient Air Quality Standards, the area may be classified as a nonattainment area. Areas with concentrations of criteria pollutants below the established NAAQS requirements are considered to be an attainment or unclassifiable area.

The SIP must be submitted to the Environmental Protection Agency for nonattainment areas. In its SIP plan, a state will develop its approach to reducing the pollutant levels in the air and any emissions of precursor pollutants, which are those pollutants that can form another pollutant in the atmosphere. The Clean Air Act's comprehensive approach to reducing criteria air pollutants covers many different sources and includes a variety of clean-up methods.

The Environmental Protection Agency maintains a list of nonattainment areas for all six principal pollutants on its Green Book Web site. Attainment designations for all states are listed in the Code of Federal Regulations. Many states publish their SIP in print or on their Web sites. It is common for states such as Pennsylvania, South Dakota, and Nebraska to have counties in both attainment and nonattainment.

Continuing Air Pollution

Air quality continues to improve across the United States, but over 40 percent of Americans still live in counties with unhealthy levels of particle or ozone pollution. According to the American Lung Association, California cities like El Centro, Fresno, Merced, Bakersfield, Los Angeles, and Modesto are at the top of the list for those with the worst year-round particle pollution. California cities also appear on the list of areas most polluted by short-term particle and ozone pollution. A combination of California's weather, agricultural methods, and vehicle and machine emissions create an air pollution hazard for the state.

Pittsburgh–New Castle, Pennsylvania; Cincinnati, Ohio; Middletown, Kentucky; and Wilmington, Indiana, also made the list for the worst year-round particle pollution. Nationally, over 131.8 million people live in areas with unhealthy pollution, up from 127 million in the 2012 American Lung Association report.

A U.S. Environmental Protection Agency researcher checking air monitoring equipment on Grand Isle, Louisiana, in 2010. There are hundreds of air quality monitors throughout the United States as part of the Ambient Air Monitoring Program.

The Clean Air Act and its National Ambient Air Quality Standards have reduced air pollution and significantly improved human health and the environment in the United States. Since 1970, the six criteria pollutants have decreased by more than 50 percent. Air pollution from large industrial sources including chemical plants, petroleum refineries, and paper mills have been reduced by nearly 70 percent, and production of most ozone-depleting chemicals has stopped. New cars are more than 90 percent cleaner and are slated to be cleaner in the future.

To counterbalance these air pollution gains, the U.S. gross domestic product (GDP) has tripled, energy consumption has increased by 50 percent, and vehicle use has increased by almost 200 percent. The balancing act between clean air, consumption, and commerce seems to be fated to continue in the 21st century.

National Energy Act of 1978

The National Energy Act (NEA) was ratified by the U.S. Congress in 1978 to address issues associated with existing and future supply, demand, and usage of energy resources. At the time of enactment, the United States was entrenched in an energy crisis resulting from inadequate domestic supplies of oil and natural gas amid swiftly escalating demand for those and other energy resources. The country was at risk of becoming more dependent on foreign energy supplies and more vulnerable to global market fluctuations and uncertainties, which could hamper the continuation of positive U.S. economic growth. The NEA was conceived as a means to empower the United States to gain better control over its energy resources, practices, and policies.

The National Energy Act is the collective name used to refer to five individual pieces of energy legislation proposed under U.S. President Jimmy Carter's National Energy Plan (NEP). It encompasses the Natural Gas Policy Act (NGPA), Public Utility Regulatory Policies Act (PURPA), Energy Tax Act, Power Plant and Industrial Fuel Use Act

(Fuel Use Act), and National Energy Conservation Policy Act (NECPA).

While modifications have been made to the various provisions over the years, the NEA largely has succeeded in bringing improved cohesion to the U.S. energy sector by way of diverse regulatory and market-based programs, initiatives, and incentives that support energy conservation, efficiencies in energy use, and alternative approaches to energy resources.

Global Context

The Organization of Petroleum Exporting Countries (OPEC) launched an oil embargo against the United States in 1973 as a protest against U.S. support for Israel during that country's territorial conflict with Egypt and Syria in October of the same year. The resulting supply shortage signaled the end of inexpensive gasoline in the U.S. market and fueled an already smoldering domestic oil crisis arising from low U.S. reserves.

Shortly after the embargo was imposed, OPEC announced that it would allow its member nations to set their own prices for their oil exports rather than continuing the practice of enabling oil companies to set their own price per barrel. As a result, the per-barrel price of oil rose by roughly 130 percent above pre-embargo pricing, representing a nearly 400 percent increase from the same period just one year earlier. The short supplies and soaring prices meant long lines at the gas pump and strong consumer demand for more fuel-efficient vehicles. American automobile manufacturers experienced sharp declines in sales of traditional gas-guzzling vehicle models and the U.S. auto industry plunged deeply into the expanding economic recession at home. The situation had reached crisis proportions by 1977.

It was against this backdrop that President Carter proposed his National Energy Plan to Congress. The original plan included more than 100 individual legislative and administrative proposals that ultimately became organized under the NEA umbrella. The components of the plan were designed to reduce U.S. dependence on foreign oil, limit supply disruptions, prepare for supply shortages caused by capacity limitations, and promote development of reliable, renewable sources of energy to facilitate sustained economic growth. Specifically, the NEA recommended an ambitious conservation program covering energy use in the transportation, building,

industrial, and power sectors as a means to reduce growth in annual energy demand. It also advocated for industry players who were using oil and natural gas as primary energy sources to convert to more prevalent forms of energy, such as coal and other fuels. Another key component of the energy plan included implementation of a rigorous research and development program aimed at providing renewable and alternative energy resources and technologies sufficient to meet domestic energy requirements. Tax incentives, pricing practices, and production policies were put in place to support the main components of the plan.

Components of the NEA

The NEA established a comprehensive national energy policy for the United States, supported by several targeted legislative acts.

The Natural Gas Policy Act (NGPA) extended price controls on sales of natural gas to include the intrastate market rather than interstate markets only. With the NGPA, all gas produced in the United States became subject to price controls. Previously, producers of natural gas took advantage of the disparity in regulatory rate control between interstate and intrastate markets and began directing the majority of their supplies to the uncontrolled intrastate market in search of greater profits from underpriced gas. As a result, there were repeated supply shortages in the interstate market, including significant shortfalls in regions served by interstate gas pipelines.

The NGPA also included provisions for phased deregulation of the wellhead price for new natural gas, which took place over the following nine years, and for an incremental pricing methodology that would distribute the expense of costly new gas to industry players versus residential users of natural gas. In addition, the act gave transportation authority to the Federal Energy Regulatory Commission (FERC). Specifically, the FERC was given the ability to authorize any interstate pipeline to transport gas on behalf of any intrastate pipeline or local distribution company without a certificate of prior regulatory approval, and likewise for any intrastate pipeline to transport gas on behalf of any interstate pipeline or local distribution company without a certificate. The provision separating natural gas transportation services from natural gas sales services marked an important step toward the

restructuring of the gas pipeline industry to create a competitive gas supply market.

The Public Utility Regulatory Policies Act (PURPA) was another key piece of regulation under the NEA. PURPA required public utilities to purchase power from independent companies that could produce power for less cost than what it would cost for the utility to produce the same level of power itself. The intent was to encourage more efficient energy production and increased development and use of renewable energy resources and technologies.

The Energy Tax Act provisions of the NEA focused on tax-based incentives to foster new energy production while reducing inefficiencies tied to price-controlled oil and gas. The tax incentives included residential energy credits aimed at encouraging consumers to make energy conservation investments for their homes. It also included business energy credits designed to encourage companies to invest in more efficient facilities and equipment and to increase production of renewable energy, alternative fuels, and high-cost natural gas. The Energy Tax Act incorporated a tax disincentive as well in the form of a gas-guzzler tax placed on low-fuel-efficiency vehicles.

The Power Plant and Industrial Fuel Use Act was implemented as part of the NEA to reduce dependence on natural gas and petroleum products. It sought to facilitate greater use of alternative energy sources by U.S. electric power plants and significant industrial installations by prohibiting those facilities from using petroleum or natural gas as a principal energy source without first receiving an exemption from the Department of Energy. When shortages in natural gas and petroleum products eased in the 1980s, the Fuel Use Act was repealed.

The final piece of NEA legislation was the National Energy Conservation Policy Act (NECPA). In addition to establishing energy-efficiency standards for new construction and strengthening energy-efficiency standards for home appliances, the act required federal agencies to conduct energy surveys in support of reducing consumption of non-renewable energy resources in buildings, vehicles, and various types of equipment. It also included a program to provide financial assistance to residential consumers to help them purchase and install solar heating or cooling equipment. Moreover, NECPA outlined an energy conservation plan for

federal buildings and created a program to provide grants and loan guarantees for energy conservation applied in schools, hospitals, local government facilities, and public housing developments.

Conclusion

With the National Energy Plan and resulting National Energy Act, President Jimmy Carter sought to increase the country's control over its own energy policies and practices. Many provisions of the NEA have been altered or abandoned in the decades since implementation in response to evolving economic and market conditions and needs. However, the conservation-focused regulations have remained largely intact and most of the market-based initiatives have been retained.

By the time President Carter left office in January 1981, the NEA had helped elevate U.S. petroleum inventories to record levels while also encouraging expansion of domestic exploratory efforts for new petroleum sources. At the same time, the NEA helped the United States generate a surplus of natural gas and devise a better means to distribute it fairly without unnecessary federal restrictions. The growth rate of U.S. coal production also doubled during President Carter's term, while imports and total consumption of oil declined significantly.

National Environmental Policy Act

Transportation projects can harm the natural, social, cultural, and historic features of the environment in many ways. To prevent or minimize harm, a number of laws and regulations have been enacted since the 1960s. However, some deleterious impacts on the environment arising from infrastructure projects are unavoidable and, therefore, are allowed, but only if appropriate steps are taken during the planning phase of the process.

The National Environmental Policy Act (NEPA) spurred the development of a set of steps and procedures to follow; these are commonly referred to as the NEPA process. By following these procedures, a state department of transportation (DOT) or other lead agency can obtain permission for transportation projects that will have environmental impacts. The project sponsor or lead agency (often a state DOT) must offer and document a reasonable justification for any action that results in some type of environmental harm. In short, the NEPA process requires the creation of a document demonstrating that the transportation project was needed, that any environmental harm that occurs is either insignificant or could not be avoided, and that steps will be taken to minimize or mitigate whatever significant harm is likely to occur. The law does not prevent adverse impacts on the environment, but it does require all federally funded projects to consider environmental factors equally to other concerns in the planning of any agency action.

Protected Resources

NEPA broadly protects the environment, but it is not the only law that requires adherence to the NEPA process, which must be followed whenever a project impacts any resources protected by federal and state laws. Section 4(f) of the Department of

Transportation Act of 1966 protects publicly owned parks or land designated or administered as public parks, publicly owned recreation areas, wildlife and waterfowl refuges, and privately and publicly owned properties either on or eligible for the National Register of Historic Places. Historic properties are also protected under section 106 of the National Historic Preservation Act. The Endangered Species Act protects plants and animals threatened by extinction. The Clean Water Act protects wetlands, as does the Mitigation of Impacts to Wetlands and Natural Habitat—Final Rule. Adverse economic and social impacts to minority and low-income residents are protected by Executive Order 12898. There are additional acts that protect archaeological resources and resources on Native American reservations and burial sites.

Actors in the NEPA Process

State DOTs are often the lead agency for a project going through the NEPA process, but they are expected to consult with other government agencies and groups representing interested parties, depending on the resources impacted. Among those frequently consulted are the Federal Highway Administration (FHWA), Fish and Wildlife, the Environmental Protection Agency (EPA), the state historic preservation offices, and tribal councils.

Oversight of NEPA is a responsibility of the Council on Environmental Quality (CEQ), which reports to the president. The CEQ is charged with reviewing environmental impact statements, but each federal agency is free to generate its own regulations for the NEPA process, which are subject to guidance from the CEQ. The NEPA process calls for a good-faith effort to avoid or minimize environmental harm. It is a process, rather than a set of specific regulations.

NEPA functions as a framework for planning. According to the act, the president, federal agencies, and courts share responsibility for enforcing NEPA, but there is no direct enforcement mechanism. Resource agencies must be consulted and can approve or disapprove a project. This can delay a project but not stop it entirely. Ultimately, the courts have the final say as to whether the process was completed in an appropriate manner. Opponents can turn to the courts to claim failure to follow the NEPA process or to argue the likelihood of unnecessary environmental harm from a project.

The NEPA Process

All government agencies that use federal money on a project and all transportation projects that are under the jurisdiction of a federal agency must follow the NEPA process. The NEPA process also applies to all projects that impact a resource protected by federal legislation or executive order. Before such projects can be constructed, they must go through the process and be reviewed by the appropriate agencies having jurisdiction. The NEPA process enables federal agencies to make better decisions by calling for a review of the possible environmental effects of a project, if any. It also calls for reasonable efforts to avoid impacts or to minimize and mitigate those that do occur.

Depending on the possibility of an environmental impact from a specific project, the NEPA process ends with the production of one of the following types of official determinations: (1) a categorical exclusion (CE), (2) an environmental assessment with a finding of no significant impact (EA/FONSI), and (3) an environmental impact statement (EIS). Environmental review can be seen as occurring in a sequence. The first step involves ascertaining if the project is on a list for a categorical exclusion. If it is not on a list, then an environmental assessment (EA) must be conducted. If the EA finds no significant impact on the environment that cannot be mitigated, an EA/FONSI is issued. However, if there is a significant impact that cannot be mitigated, then an EIS must be produced.

A project can qualify for a CE if it is on a list of actions that have been determined to not result in significant environmental impact. Each federal agency creates its own list of CEs. The FHWA, for instance, lists these types of projects as potential CEs: construction of bicycle and pedestrian lanes, noise barriers, landscaping, and installation of signs and pavement markings.

As stated in 40 CFR 1508.9(a), an EA has three functions: (1) provide sufficient evidence and analysis for determining whether to prepare an EIS or a FONSI, (2) aid in agency's compliance with the act when no EIS is necessary, or (3) facilitate preparation of an EIS when one is necessary. Public hearings may be held but are not required. The completed EA will have these elements: the purpose and need for the project; alternatives, including the no-build option; the environmental impacts, if any, of the proposed action and of alternatives, along with the

mitigations that render the impacts insignificant; and a listing of the agencies and persons consulted. If the EA results in a FONSI, then it must contain an explanation of the reason(s) the project will not produce a significant environmental impact.

If a significant environmental impact is likely and cannot be mitigated, the agency must produce an EIS, which will require more intensive effort and resources. Often, there are two phases to the EIS process: the draft EIS (DEIS) and the final EIS (FEIS). The public responds to the draft, and those comments and concerns are addressed in the FEIS.

The EIS process begins with the lead agency, such as a state DOT, filing a notice of intent in the *Federal Register*, which describes the proposed action and scope. This invites public participation in defining the scope.

The EIS—draft or final—must describe indirect and cumulative effects, as well as direct effects from the project. Indirect effects include the growth-inducing effects of a project and related changes in land use, as well as changes in population density and long-term effects on air, water, and other natural resources.

As a general rule, a legally sufficient EIS will include (1) a purpose and need statement that clearly articulates the benefits arising from the project; (2) a description of the project and the area to be impacted; (3) a full discussion of the alternative routes or designs considered, including the no-build alternative, with explanations for the respective dismissals of the alternatives; (4) a description of all impacts—direct, indirect, and cumulative; (5) an account of public participation and coordination with appropriate resource agencies; (6) an evaluation of any issues raised by the public and the agencies, and (7) a discussion of measures taken to minimize or mitigate any adverse effects arising from the project. In the words of FHWA, the NEPA document must “adequately describe the reasons for a factual conclusion or decision on the issue and account for new information or circumstances.”

The lead agency sends copies of the DEIS to the EPA and “any federal agency that has jurisdiction by law or special expertise in respect to any environmental impact, or that is authorized to develop and enforce environmental standards.” Those agencies’ comments must be obtained. Comments are also requested from “appropriate state and local agencies authorized to develop and enforce environmental

standards; Indian tribes (when a reservation may be affected); ... and the public, especially persons or organizations that may be interested or affected.” The EPA then publishes a Notice of Availability of the DEIS in the *Federal Register*.

After receiving all comments, the EPA then reviews the DEIS and rates its environmental impact and adequacy of information. If the document is rated environmentally unsatisfactory, the EPA refers the document to the CEQ, which then attempts to resolve disputes between the lead agency and the EPA.

Upon completion of the public review and comments, the lead agency incorporates the comments into the FEIS. The FEIS is submitted for public review and submitted to the EPA (and CEQ) for review. The EPA then adds comments on the unresolved issues, if any, that arose during the review of the DEIS and notes any new significant impacts, if any, not previously discussed. The EPA then reviews the FEIS and issues a record of decision (ROD) in which it comments on the lead agency’s choice among the alternatives. The ROD becomes a public document published in the *Federal Register*.

Expediting the NEPA Process

For large and complex projects, the NEPA process can be rather time consuming and labor intensive. In response, there have been several efforts to expedite the process or make it more flexible. FHWA is actively promoting the expanded use of programmatic agreements (PAs), which are documents that spell out the terms of a formal, legally binding agreement between a state DOT and other state and/or federal agencies. With PAS, projects can be reviewed more quickly and project delivery time shortened.

To facilitate mitigation, states are now encouraged to create programs for wetland mitigation banking. There are several advantages to wetland mitigation banking, including ecological benefits for larger land areas, reduced reporting and monitoring time, and expedited processing and review of permits.

In the interest of clarifying the conditions under which a protected property could be used, Section 4(f) of the Department of Transportation Act of 1966, one of the most stringent of the environmental protection laws, was revised in 2008. Once there has been a determination that there is no prudent

alternative to the use of protected property, DOTs can now consider the costs of alternatives, as well as other factors (23 CFR—Part 774).

National Highway System Designation Act of 1995

When Congress passed the Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA), the legislature instructed the Department of Transportation (DOT) to submit a proposal for a National Highway System (NHS) to Congress by September 1995. No funds were released for the project until Congress passed the National Highway System Designation Act of 1995 (S. 440), which President Bill Clinton signed into law (P.L. 104-59) on November 28, 1995.

The National Highway System Designation Act appropriated \$5.4 billion for highways and other transportation infrastructure projects. The chief purpose of the act was to determine which highways throughout the United States should be considered of "national significance" because of the

links they provided to other forms of transportation and to defense and military facilities. Even though those highways made up only 4 percent of the total number of U.S. highways, they handled 90 percent of all tourist traffic and 75 percent of all heavy-truck traffic on the nation's highways. (Designated roads in Puerto Rico were also included in the NHS.) Because 90 percent of the population live within roughly 5 miles of an NHS road, the entire country has become connected by the NHS.

Designating strategic highways as part of the NHS was also intended to provide cohesion to the transportation sector as a whole. In addition to linking key areas within the United States, the system provides 53 links to Canada and Mexico to facilitate the movement of goods across national borders. Another key element in the NHS Designation Act of 1995 was to improve highway safety throughout the United States.

National Highway System

In 1996, in the spring issue of *Public Roads*, which celebrated the NHS, Federal Highway Administrator Rodney Slater called the NHS the cornerstone of the effort to prepare the American transportation sector for the 21st century. As instructed by Congress in the Intermodal Surface Transportation Efficiency Act, officials from the Federal Highway Administration (FHWA) and the DOT worked closely with state and local governments and metropolitan planning organizations to identify roads within particular areas that should be included in the NHS.

While the interstate system accounts for some 30 percent of roads identified under the NHS Designation Act, most roads within the network are two-lane paved roads. Altogether, the NHS encompasses 161,000 miles of roads. According to the FHWA, the NHS is made up of five parts. The first of these is the Eisenhower Interstate System. The second section is comprised of high-priority corridors that were designated by the ISTEA. These roads serve as connectors, providing access to major transportation facilities such as ports and airports. The third section of NHS is comprised of approximately 61,000 miles of the Strategic Highway Network (STRAHNET), which is made up of strategically significant highways that are important to defense. A fourth section of the NHS is comprised of some 2,000 miles of connector roads that link major defense and military installations to STRAHNET. The final

A highway sign acknowledges the official designation of the interstate highway system as the Dwight D. Eisenhower National System of Interstate and Defense Highways. Eisenhower's role in the Federal Aid Highway Act of 1956 was crucial to the project.

section is comprised of all the roads that connect major intermodal facilities with the rest of the NHS. Taken as a whole, the NHS serves 198 ports, 207 airports, 67 Amtrak stations, 190 rail/truck terminals, 82 intercity bus terminals, 307 public transit stations, 37 ferry terminals, 58 pipeline terminals, and 20 multipassenger terminals.

Background

World War II hero General Dwight D. Eisenhower was elected president of the United States in 1952. In 1919, Eisenhower had participated in the War Department's Transcontinental Motor Convoy, which traversed the United States on two-lane roads that were in varying conditions of repair. With his military experience, Eisenhower was successful as president in pushing through the Federal Aid Highway Act of 1956, which established the interstate highway system in the United States. Congress was motivated by the need to emphasize defense and to

improve road travel during the Cold War, and the interstate system was officially designated as the Dwight D. Eisenhower National System of Interstate and Defense Highways. Although the system was set to be completed in 1969, it was another decade before it was finished. Delays were often caused by local officials vying to have their towns connected to the interstates, which were likely to bring tourists and much-needed revenue.

The interstate system used standardized design in order to enhance safety, functionality, and aesthetics. The standards were developed by state highway agencies working in conjunction with the American Association of State Highway and Transportation Officials (AASHTO). The design called for full control of access and the capability of handling speeds from 50 to 70 miles per hour. All roads were required to be at least two lanes in each direction, and it was stipulated that those lanes be 12 feet wide and contain a 10-foot right paved shoulder and a four-foot paved left shoulder.

In 1968, the Federal-Aid Highway Act expanded the interstate system to 42,500 miles and gave the secretary of transportation the authority to designate existing highways as part of the interstate system, as long as the roads met interstate standards. Five years later, the Federal Aid Highway Act of 1973 added another 500 miles to the system. Subsequently, the Surface Transportation Assistance Act of 1978 provided full funding for routes included in the interstate system, but ended funding for new interstate construction. The interstate system became an integral part of the NHS in the mid-1990s, and the standardization of roads enhanced their ability to facilitate movement during emergencies.

Provisions

In 1992, while campaigning for president, Bill Clinton and Al Gore, vice presidential candidate, crisscrossed America on buses. During that trip, Clinton first perceived the advantages of linking all highways in the nation through a national system. However, the bill that made it through Congress was not the bill that Clinton, as president, had sent to the legislature. When signing the bill, Clinton promised to keep working toward mitigating the impact of elements that had been removed from the bill.

Those key elements concerned the removal of a provision that would have forced states to enact

a national maximum speed limit, and toughened laws on the use of motorcycle helmets. The president's other concerns focused on exemptions that Congress had allowed for small-to-medium-sized trucks in the areas of driver qualifications and truck maintenance.

States were given considerable flexibility in using the funds appropriated by the bill, which removed existing requirements forcing states to comply with federal standards in building materials and program management. States were permitted to modify the map of designated highways within their boundaries, but only after submitting proposals for modifications to the secretary of transportation, who then submitted the proposed modifications to designated congressional committees for approval.

The Intermodal Surface Transportation Efficiency Act of 1991 had paved the way for the designation of four high-priority corridors as part of the interstate system, and Congress stipulated that all highways designated as Congressional High Priority Corridors under ISTEA be included in the NHS. The NHS Designation Act of 1995 also amended Section 1105 of ISTEA, which had divided surface transportation assistance funding among highways, bridges, railways, transit systems, bike paths, and walkways. In 1998, the Transportation Equity Act for the 21st Century modified the description of three of the four corridors and designated five additional corridors for future inclusion in the interstate program.

When debating passage of the NHS Designation Act, Congress was forced to contend with the fact that enactment of the ISTEA had reduced highway funding significantly. Because those reductions were estimated to amount to \$2.7 billion in 1996, the act sought to provide states with another means of obtaining federal funding for critical projects by allowing them to decide what their priorities should be.

Safety was a major element of the NHS Designation Act. The bill included a provision enacting the president's zero-tolerance policy toward young people driving under the influence of alcohol (DUI), which was designed to force states to exact tough penalties for DUI offenses by anyone under the age of 21 by withholding funds from states that refused to pass this legislation. In 1995, when the bill was passed, studies had shown that states with zero-tolerance laws were reporting 20 percent fewer

alcohol-related accidents than those states that did not have such laws.

Congress went against Clinton's attempts to make adopting the national maximum speed limit a requirement for receiving NHS funding, but it did require the secretary of transportation to submit a report detailing the human and economic costs to each state that chose to allow a maximum speed above the federal standard. The president also failed to convince Congress to maintain state laws mandating the wearing of motorcycle helmets by withholding federal funds from highway construction.

The NHS Designation Act authorized the \$2.55 million needed to extend the National Highway Traffic Safety Administration for an additional year. It also authorized a pilot program to exempt vehicles weighing between 10,000 pounds (4,500 kilograms) and 26,000 pounds (11,700 kilograms) from the Federal Motor Carrier Safety Regulations. Eligibility for the exemption was based on specific criteria and was dependent on maintaining an acceptable safety rating.

National Highway Traffic Safety Administration

The National Highway Traffic Safety Administration (NHTSA) was established by the Highway Safety Act of 1970. Under the direction of the U.S. Department of Transportation, NHTSA's objective is to reduce deaths, accidents, and economic losses from motor vehicle collisions. One of the leading causes of death for 1- to 34-year-olds is vehicular crashes, with a loss of over 30,000 lives per year in the United States, a decrease from previous years. In 2009, 630 cyclists and 4,092 pedestrians were killed in traffic crashes within the United States, making pedestrian safety a focal concern of the NHTSA. In addition, there are 3.2 million crash-related injuries annually. Tasks of the NHTSA include the following:

- Investigate safety defects in motor vehicles
- Set and enforce fuel economy standards
- Help states and local communities reduce the threat of drunk drivers
- Promote the use of safety belts, child safety seats, and air bags
- Investigate odometer fraud
- Establish and enforce vehicle antitheft regulations
- Provide consumer information on motor vehicle safety topics

For 2014, NHTSA proposed a budget of \$828.3 million to address roadway safety, which is comprised of \$561.5 million for state grants and high visibility enforcement support, \$148.3 million for vehicle safety, and \$118.5 million for behavioral safety. This is \$26.8 million higher than the 2013 budget. Funding for Highway Safety Research and Development and Highway Traffic Safety Grants is mandatory, attributed to the Transportation Trust Fund (TTF). Because Vehicle Safety Research funding and spending is attributed to the General Fund (GF), it is discretionary.

Behavioral Safety

The NHTSA expenditures on behavioral safety focus on impaired driving and occupant safety. Through initiatives in education, in conjunction with law enforcement, the NHTSA has shown marked decreases in injuries and deaths. By seeking to sustain participation with criminal justice agencies, the NHTSA supports the Data-Driven Approaches to Crime and Traffic Safety (DDACTS) program, conducted in partnership with the Department of Justice. The NHTSA also plans to contribute to the National Drug Control Strategy program produced by the Office of National Drug Control Policy.

The Click It or Ticket (CIOT) campaign is a broad-scale approach to increase seatbelt use, and to further enhance the biannual (Labor Day and December) anti-distracted-driving campaigns. Eighteen percent of vehicular crashes in 2010 were caused by distraction-related incidents. Drivers who were text-messaging while driving were 27.7 times more likely to be involved in an accident. This is particularly significant when compared with other activities. For example, drivers who were reading a book or newspaper while driving were only 4.8 times more likely to be involved in an accident.

Reductions in pedestrian crashes, which disproportionately affect children, older adults, and Hispanics, are targeted through behavioral initiatives, including education and law enforcement. The NHTSA has supported "Pedestrian Focus Cities" and "Focus States" with the education and enforcement components of its Pedestrian Safety Action Plans. These initiatives have led to a decrease in pedestrian-related incidents. While efforts have been focused particularly in Florida, New Mexico, North Carolina, and the city of Chicago, the NHTSA will continue to conduct demonstrations

to help law enforcement agencies implement the “Standardized Pedestrian Crosswalk Enforcement” program and other components of the Pedestrian Safety Action Plan.

Research

The NHTSA focus on vehicle safety centers around research. Critical research areas include vehicle structure and restraints, human biomechanics, crash avoidance and human factors, heavy vehicle safety, alternative-fuel vehicle safety, and connected vehicle research.

Much of the NHTSA research on structure and restraints focuses on the use of hydrogen fuel. Examples of recent studies include an analysis of hydrogen vehicle safety, fuel system life cycles and durability, and fire safety research regarding both localized and post-crash leakage.

A significant amount of current research is devoted to crash avoidance and the human aspects of transportation. Examples of current, ongoing studies by the NHTSA in the category of crash avoidance, human biomechanics, and human factors research include the following: biomechanical investigations using human surrogates; brain injury criteria for 6- to 10-year-old children; development of advanced instrumentation, test procedures, injury criteria, and injury analysis software for crash test analysis that can be used for all individual injury modes; and distraction detection and mitigation through driver feedback.

While not a significant focus of current research efforts, NHTSA's heavy vehicle safety research includes commercial vehicle rollover prevention technology and hardware-in-the loop analysis for heavy truck electronic stability control (ESC).

Alternative Fuel Vehicle Safety/ Corporate Average Fuel Economy (CAFE)

The purpose of CAFE is to reduce energy consumption through enhanced fuel economy of cars and light trucks. Joint Final Rules for Corporate Average Fuel Economy and Greenhouse Gas Emissions regulations for model years beginning in 2017 are recent standards set by the NHTSA in coordination with the Environmental Protection Agency (EPA). These regulations aim to help address U.S. dependence on imported oil, save consumers money at the pump, and reduce emissions of greenhouse gases that contribute to global climate change.

State Grants and Enforcement Support

For 2014, the NHTSA requested funding for a new incentive grant program to encourage states to enact laws that prevent distracted driving, such as the following:

- Laws restricting cellular phone use and texting while driving
- State graduated driver licensing laws programs, including a two-stage licensing process for young drivers
- An In-Vehicle Alcohol Detection Device Research program, which supports discretionary research on in-vehicle technologies designed to prevent alcohol-impaired driving

In addition to support of new initiatives, the NHTSA continues to support existing state grants and high-visibility enforcement in such areas as child safety and booster seat incentives, impaired driving countermeasures, motorcyclist safety, occupant protection incentives, and state traffic safety information system improvements, as well as funding NHTSA's annual media campaigns.

The U.S. Department of Transportation's National Highway Traffic Safety Administration (NHTSA) has a broad and far-reaching objective to reduce deaths, accidents, and economic losses from motor vehicle collisions. Through its work in research, behavioral safety, state grants, and high-visibility enforcement support, the NHTSA has been effective in reducing the number of deaths, injuries, and economic costs associated with the ever growing transportation system in the United States.

- The public’s view of the adequacy of transportation systems and services

National Household Travel Survey

Since 1969, the National Household Travel Survey (NHTS), previously known as the Nationwide Personal Transportation Survey (NPTS), has been an established U.S. Department of Transportation (DOT) program. The NHTS is the DOT’s only inventory of passenger travel. The data are used to determine current travel characteristics, such as the relative proportion of travel by mode (for example, vehicle, transit, and walk) and purpose (for example, work, school, family/personal, and recreation) by residents of U.S. households. These data allow the DOT to evaluate the adequacy of existing transportation facilities and estimate future needs. The NHTS is consolidated with other data to provide a biannual report to Congress. The major portion of funding for the survey has come from the Federal Highway Administration, but in 2001 the Bureau of Transportation Statistics contributed a significant amount along with other DOT agencies.

In addition, data from the NHTS serves to answer important questions from the secretary of transportation’s office, Congress, state and local departments of transportation, researchers, and the media on current characteristics of travel by the American public, including the following:

- Factors that affect the use of private vehicles, carpooling, and alternative modes

Seven national travel surveys have been conducted in the following years: 1969, 1977, 1983, 1990, 1995, 2001, and 2009. The NHTS is the only national authoritative source to obtain current information on national patterns of travel to better understand travel behavior, evaluate the use of transportation facilities, and gauge the impact of the department’s policies and programs. It helps measure the performance of the surface transportation systems in the United States, including the efficiency, safety, energy use, air quality, congestion, active health measures, and intermodal transportation systems. It serves transportation researchers, planners, and policy makers with comprehensive data on travel and transportation patterns in the United States.

Data Collected

The 2009 NHTS provides information to assist transportation planners and policy makers who need comprehensive data on travel and transportation patterns in the United States. The NHTS/NPTS serves as the nation’s inventory of daily travel. Data is collected on daily trips taken in a 24-hour period and includes the following:

- Purpose of the trip (work, shopping, etc.)
- Means of transportation used (car, bus, subway, walk, etc.)
- How long the trip took, that is, travel time
- Time of day when the trip took place
- Day of week when the trip took place
- Number of people in the vehicle (vehicle occupancy); driver characteristics (age, sex, worker status, education level, etc.) and vehicle attributes (make, model, model

year, amount of miles driven in a year) for private vehicle trips

These data are collected for all trips, modes, purposes, trip lengths, and areas of the country, including both urban and rural.

Uses and Scope of NHTS

NHTS data are used to quantify travel behavior, analyze changes in travel characteristics over time, relate travel behavior to the demographics of the traveler, and study the relationship of demographics and travel over time.

The NHTS data are used primarily for gaining a better understanding of travel behavior. The data enable DOT officials to assess program initiatives, review programs and policies, study current mobility issues, and plan for the future. It has also been a tool in the urban transportation planning process because it provides personal travel behavior trends, trends in travel over time, trip generation rates used to benchmark when comparing local data, and data for various other planning and modeling applications.

The transportation research community, including academics, consultants, and government, use the NHTS extensively to examine travel behavior at the individual and household level; the characteristics of travel, such as trip chaining, use of the various modes, amount and purpose of travel by time of day and day of week, vehicle occupancy, and a host of other attributes; the relationship between demographics and travel; and the public's perceptions of the transportation system.

People in various fields outside transportation use the NHTS data to connect the role of transportation with other aspects of life. Medical researchers use the data to determine crash exposure rates of drivers and passengers, including the elderly, who have heightened morbidity and mortality rates. Safety specialists study the accident risk of school-age children, particularly when they are traveling on their own by walking or biking. Social service agencies need to know more about how low-income households currently meet their travel needs.

The scope of the 2009 NHTS data set includes, but is not limited to, the following:

- Household data on the relationship of household members, education level,

income, housing characteristics, and other demographic information

- Information on each household vehicle, including year, make, model, and estimates of annual miles traveled
- Data about drivers, including information on travel as part of work
- Data about one-way trips taken during a designated 24-hour period (the household's travel day), including the time the trip began and ended, length of the trip, composition of the travel party, mode of transportation, purpose of the trip, and the specific vehicle used (if a household vehicle)
- Information to describe characteristics of the geographic area in which the sample household and workplace of sample persons are located
- Data on telecommuting
- Public perceptions of the transportation system
- Data on Internet usage
- Typical number of transit, walk, and bike trips made over a period longer than the 24-hour travel day

In the past, there have been many requests for data that are closely related to but are not available in the survey. Examples of the most common requests for data that are not included in NHTS are the following:

- Information on costs of travel
- Information about specific travel routes or types of roads used
- Travel of the sampled household changes over time
- Information that would identify the exact household or workplace location
- The traveler's reason for selecting a specific mode of travel over another mode

Add-On Samples

A key function of the NHTS has been the inclusion of an add-on program, in which states and metropolitan planning organizations have the unique opportunity to purchase additional samples for their jurisdiction through a pool funding mechanism operated by the Federal Highway Administration. These additional samples, along with random

national samples collected in the add-on area, are compiled into a cleaned geocoded database for ready application to local planning and forecasting. Trips of all lengths, for all purposes, and for all modes are collected.

The add-on program started with five state and metropolitan planning organizations in 1985 and grew to 20 members in 2009. In 2009, it provided one of the largest household sample sizes of over 151,000 household interviews with over 320,000 individual interviews that represented all 50 states.

Design, Implementation, and Sample

In general, the survey designs have changed over the years, starting with face to face in 1969 and 1977 and then switching to telephone. In 2001 it was a list-assisted random digit dialing (RDD) computer-assisted telephone interviewing (CATI) survey conducted over an entire year. Eligible households were in the civilian, noninstitutional, and noninstitutionalized population of the United States. People living in medical institutions, prisons, and in barracks on military bases were excluded from the sample.

National Mass Transportation Assistance Legislation

In the mid-1970s, the ever increasing number of fossil-fuel-burning vehicles on U.S. roads was not only leading to intense traffic congestion in many cities but was also generating concerns about the damage that those fuels exerted on the environment. Consequently, mass transit began to receive greater attention.

In 1974, Congress enacted the National Mass Transportation Assistance Act (P.L. 93-503), which authorized \$11.8 billion in federal funds for mass transit projects. It was the first time that federal funds had been designated for assisting individual states and cities in meeting operating expenses for mass transit systems. The bill also earmarked funding for public transportation in rural areas.

President Gerald Ford signed the bill into law on November 26, 1974. During the signing ceremony, Ford acknowledged that passage of the bill had not always run smoothly, but he praised members of Congress for working together to reconcile the many differences that had surfaced during the course of the bill's becoming law. In 1978, Congress worked with the administration of President Jimmy Carter to extend funding for assistance to mass transit. In 1982, under President Ronald Reagan, the administration failed to win support in its attempts to drastically slash mass transit assistance, but it did manage to redesign the formula for receiving assistance with the Federal Public Transportation Act of 1982.

Earlier Federal Actions

Because funds were lacking during the Great Depression and gasoline rationing placed additional pressure on mass transit during World War II, most U.S. transit systems were in serious need of repair by the 1950s. Many companies faced bankruptcy.

In 1961, Congress made its first move toward restoring mass transit by providing funding for commuter railroads in the Housing Act. By 1962, politicians and the general public were coming to see the need for federal assistance for the mass transportation sector. That year, in a speech to Congress, President John F. Kennedy urged the national legislature to pass new transportation legislation to

assist cities and regions in expanding access to mass transit. Such a move, he insisted, was necessary for promoting urban renewal.

It was not until two years later, however, that Congress passed the Urban Mass Transportation Act of 1964 as part of President Lyndon Johnson's Great Society reforms. The 1964 act established a 12-year, \$375 million program of grants and loans, which was designed to fund the improvement and expansion of mass transit programs. This was a major victory for the transportation sector.

The federal grant program established in the bill provided assistance of up to two-thirds of the capital costs involved in constructing and acquiring facilities and in purchasing equipment. The rationale behind the act was that the influx of federal funds would spur local investors to supply the remaining one-third needed to create and improve mass transit systems. Studies that examined the growth of mass transit in the period following the act's passage indicated that the number of publicly owned transit systems grew from 58 in 1965 to 308 in 1974.

The 1964 act also established the Urban Mass Transportation Administration (UMTA) under the auspices of the U.S. Department of Transportation. In its early days, one of UMTA's major functions was to help cities buy bus companies that were failing, thereby ensuring that mode of public transportation survived. Within five years of the passage of the act, only \$700 million in federal money had been used to fund 148 mass transit projects. In the Urban Mass Transportation Assistance Act of 1970, Congress broadened the scope within which federal funds could be used.

Mass Transportation Assistance Acts of 1974 and 1978

When Congress addressed the issue of federal aid to mass transit within the context of the National Mass Transportation Assistance Act of 1974 (P.L. 93-503), the United States was experiencing a trend toward revenue sharing according to designated mathematical formulas. Members of Congress from rural areas, who dominated a number of congressional committees, opposed the measure because they were extremely reluctant to direct large chunks of federal funds to urban areas. As a compromise measure, the bill set aside funds that could be used for either operating costs or for capital expenses.

Half of federal funds received under the provisions of the act could be used to defray operating expenses. However, access to those funds was limited by Section 5, which stipulated that funds be allotted according to population. In areas with populations greater than 200,000, funds were given directly to the recipient. States were assigned responsibility for dispensing funds to areas with populations between 50,000 and 200,000. Ultimately, approximately 87 percent of funds dedicated to mass transit grants under the 1974 act were used for operating expenses. The 1974 act also granted new concessions to the elderly and the disabled by requiring that they be charged half-fares on mass transit systems when traveling during nonpeak time periods.

Since the 1974 bill had funded mass transit assistance through 1979, Congress was again set to consider new policy on the issue as the decade drew to a close. By 1977, when Secretary of Transportation Brock Adams began working with key senators to develop a funding plan that met the requirements of the Carter administration without causing major upheaval, large cities such as New York and Washington, D.C., already had a backlog of projects because of a lack of funds. The Senate plan called for a \$5.7 billion appropriation to fund assistance to mass transit for the following five years. While that funding was considered a victory in light of Adams's earlier insistence that no new funds were needed for mass transit assistance, it was considerably less than the \$11.4 billion called for in a bill sponsored by Senator Harrison A. Williams (D-NJ).

The 1978 bill extended the reach of the National Mass Transportation Assistance Act by allowing recipients of mass transit assistance to use such funds for capital expenses and for operating fixed-rail projects. The 1978 Federal Public Transportation Act, Title III of the Surface Transportation Assistance Act of 1978 (P.L. 93-599), also created metropolitan planning organizations (MPOs). Bowing to pressure from large cities that argued that the formula used in assistance grants should be based on the scope of transit services rather than on population, the 1978 bill initially provided a compromise, establishing a tier system for grants allotted under Section 5. One tier granted 85 percent of federal mass transit funds to cities with populations of more than 750,000. Another tier earmarked funding for cities with subways. An additional tier protected the needs of smaller

cities by funding the purchases of buses to be used for public transportation. Transportation Secretary Neil E. Goldschmidt suggested abolishing the proposed tier system, and the Senate complied, delighting urban lobbying groups.

The 1982 Bill and Beyond

In 1982, the United States was experiencing a major economic recession and one of Reagan's suggested cutbacks was to eliminate all federal assistance geared toward operating mass transit programs. In response to intense controversy, Reagan agreed to support funding through block grants as part of the Federal Public Transportation Act of 1982, Title III of the Surface Transportation Act of 1982 (P.L. 94-424). However, the Reagan administration insisted on the provision that federal assistance be capped at 80 to 95 percent of previous levels. The 1982 act also established a one-cent tax on each gallon of gas purchased at the pump. Funds from the tax were placed in the Highway Trust Fund to cover the grant program.

Five years later, Congress overrode a presidential veto of the Federal Mass Transportation Act of 1987 (P.L. 100-17) to increase the federal-assistance caps by 32.3 percent for cities with populations over 200,000. At that time, Congress allotted 40 percent of grant funds to constructing and extending transit lines, 40 percent to modernization programs, and 10 percent to funding major bus projects. The final 10 percent was dedicated to a discretionary grant program. A subsequent bill, the Federal Transit Act Amendments, passed in 1991 as part of the Intermodal Surface Transportation Efficiency Act of 1991 (P.L. 102-240), shifted the discretionary fund allotment to bus projects.

1998 Amendments

In 1998, the Federal Transit Act, Title III of the Transportation Equity Act for the 21st Century (P.L. 105-178), provided an additional \$41 billion in federal funding for mass transit. Even though federal assistance to mass transit increased during the 1990s, state and local governments began to take on more responsibility for their own systems, contributing some 60 percent of funds spent on mass transit during the decade. Together, the Intermodal Surface Transportation Efficiency Act of 1991 and the Transportation Equity Act for the 21st Century, enacted in 1998, promoted greater flexibility

in using federal funds for meeting individual transportation needs in states and cities, with funds able to be divided between highways and mass transit.

National Railroad Passenger Corporation/Amtrak

The National Railroad Passenger Corporation is better known as Amtrak, a name that is derived from

the words *America* and *track*. Amtrak was created as a federally subsidized mass transit system.

While most large cities provide mass transit through local or regional systems, Amtrak has historically been the only system that connects geographically distant cities. Amtrak works closely with passenger lines owned by states, such as the Virginia Railway Express, and by regions, such as the Massachusetts Bay Transportation Authority. In 2012, some 28 million passengers used the 300 trains operated by Amtrak that ran on 21,000 miles of track. Forty-six of the 50 states, as well as Washington, D.C., and parts of Canada, are currently connected by Amtrak. Only Alaska, Hawai'i, South Dakota, and Wyoming are not part of Amtrak's route.

The most widely used network within Amtrak, which transports some 300,000 passengers each day, is the Northeast Corridor, covering 450 miles and connecting cities including New York, Boston, and Washington, D.C. While Amtrak has consistently delivered on its promise of preserving passenger trains, the company has not always been financially stable. Between 1971 and 2002, Amtrak received an average of \$760 million a year in government subsidies, amounting to a total of \$25 billion. Even so, government funding for Amtrak has been considerably less than amounts spent on supporting highways and aviation during that same period.

Preserving Passenger Railways

Despite the importance of railroads to the founding of the United States and the essential role they played in the Industrial Revolution, the increase in automobile ownership and the creation of a national highway system, coupled with the rise in air travel, meant that the need for passenger railroads began to diminish over the course of the first half of the 20th century.

Passenger trains had virtually disappeared in the United States by the 1960s. In an effort to save them, officials began pressuring President Richard Nixon to agree to government subsidies of private railways, but Nixon was reluctant to commit to that action. Instead, Congress passed the Rail Passenger Service Act of 1970, which established the National Railroad Passenger Corporation (Amtrak) as a quasi-public passenger rail system.

Amtrak initiated operations on May 1, 1971, and the first train left Pennsylvania Station in New York City on its way to Philadelphia. Amtrak operated 184

An Amtrak Downeaster route train in Wakefield, Massachusetts, in November 2012. Amtrak's Northeast Corridor serves as many as 300,000 people every day on the railways between Washington, D.C., and Boston, Massachusetts.

trains in that first day in business. Initially, Amtrak's train stock was highly diverse. Railroad historians and train buffs dubbed the period "the Rainbow Era" because most of Amtrak's cars had been purchased from other companies. It took three years; but in 1974, Amtrak introduced the red, white, and blue color scheme that became familiar in many cities throughout the United States.

In 1972, Amtrak's service was extended to Canada, connecting designated American cities with Vancouver, British Columbia, and Montreal, Quebec. The following year, the Regional Rail Reorganization Act transferred service for the Northeast Corridor to Amtrak. In 1978, Congress passed the Amtrak Improvement Act, and the administration of President Jimmy Carter began looking into ways to make Amtrak more profitable.

When Conrail, the government-subsidized freight railway service, ran into major financial problems in

the early 1980s, officials were forced to turn their short-haul commuter operations over to Amtrak under the auspices of the newly created Amtrak Commuter Services Corporation. By 1981, Amtrak had placed 1,436 new or rebuilt electric railcars into operation. In 1992, for the first time, commuters comprised the largest segment of Amtrak's passengers, and six years later, the company recorded passenger-generated revenues of more than \$1 billion.

Disaster and Recovery

Throughout the 1980s and 1990s, Amtrak borrowed money from private lenders, paying it back out of government subsidies. In 1996 and 1997, Amtrak reported overall losses of \$764 million and \$762 million, respectively, and began scaling back its operations. Congress responded by passing the Amtrak Reform and Accountability Act of 1997, which mandated self-sufficiency. Amtrak officials reacted by proposing that the company be split into two entities, separating Northeast Corridor operations from all others.

In 2000, high-speed rail (HSR) was introduced to Amtrak's Northeast Corridor. Powered by electricity, these trains were capable of speeds up to 150 miles per hour, which significantly cut down commuting time. Thus, it was possible to travel between Washington, D.C., and New York City in 2 hours and 45 minutes. Many railway enthusiasts saw HSR as a way to save passenger rail service in the United States, and they wanted to expand its use throughout Amtrak's networks. One of their strongest arguments was the potential role that HSR could play in protecting the environment. The Environmental Law and Policy Center reported that HSR is three times more fuel efficient than automobiles and six times more fuel efficient than airplanes. Thirty-four states invested \$1 billion in building 10 HSR corridors.

The period following the terrorist attacks of September 11, 2001, saw a brief rise in Amtrak's passenger count as fear of air travel became common. By 2002, Amtrak was operating 265 trains per day, and 23.5 million passengers per year were traveling along the 23,000 miles that made up Amtrak routes in 500 cities.

However, problems arose as a result of several accidents that occurred that year. The first occurred in Crescent City, Florida, on April 18, when two railcars derailed as a result of a perceived

track misalignment, killing four passengers and injuring 150 others. On July 20, a train traveling from Chicago to Washington, D.C., derailed in Maryland following a heat-induced track misalignment, injuring more than 100 passengers. Then, on August 21, a third derailment occurred in San Jose, California, when an Amtrak train struck a piece of metal deposited on the track by a freight train, resulting in seven injuries. All of these incidents damaged both railcars and tracks, and Amtrak's situation became more dire after it was discovered that tracks between Washington, D.C., and Boston had cracks.

The very existence of Amtrak began to be hotly debated. Supporters maintained that mass transit was essential to reducing global warming, cutting down on highway congestion, and curtailing urban sprawl. They also argued that it served as an economic stimulant by spurring growth in urban areas. Those on the other side of the argument contended that rail travel in the United States should be relegated to history, and they strenuously objected to billions of federal dollars being poured into subsidizing Amtrak. It was a crucial point in Amtrak's history because the company was on the brink of financial collapse. In order to stave off bankruptcy, supporters convinced President George W. Bush to release \$100 million in emergency loans, and Congress approved an additional \$205 million.

By 2006, Amtrak was on the road to recovery, reporting record revenues in November. In 2008, Congress passed the Passenger Rail Investment and Improvement Act, reauthorizing Amtrak and paving the way for additional improvements to the system. In 2009, under President Barack Obama's American Recovery and Reinvestment Act, Amtrak received \$1.3 billion to improve operations further, and another \$8 billion was set aside for working with states to develop intercity and high-speed rail networks. In 2011, Amtrak received a \$562.9 million loan from the Federal Railroad Administration for the purchase of 70 new energy-efficient and high-performing electric locomotives, representing an important step toward Amtrak's future as an efficient, environmentally sustainable, and desirable means of mass transportation.

National Transportation Safety Board

The U.S. Congress established the National Transportation Safety Board (NTSB) in 1967 in order to streamline and improve government safety oversight of the transportation system. The NTSB's main function is the investigation of transportation accidents within its jurisdiction and the issuance of safety recommendations. Aircraft accident investigations are one of the NTSB's primary and most public functions. Aircraft accidents received heightened media attention after World War II as skies became more congested, passenger loads increased, and accidents involved larger commercial aircraft and claimed larger numbers of victims.

The NTSB is only authorized to investigate aviation accidents within U.S. territory or in international waters, but it often sends representatives to

assist foreign government investigations of overseas accidents involving U.S.-based air carriers or aircraft manufactured within the United States, which represents much of the world's carrier fleets.

NTSB accident investigations encompass a variety of civil transportation modes, including aviation, highway, marine, pipeline, and railroad. The agency also investigates accidents related to hazardous material transportation. NTSB statistics list annual agency investigation rates at approximately 2,000 aviation incidents and accidents, as well as approximately 500 accidents involving other modes of transportation. Historical statistics list over 130,000 aviation accidents and thousands of surface transportation accidents investigated, along with the issuance of over 13,000 safety recommendations.

On-call expert "Go Teams" form the core of NTSB accident investigation, issuing accident reports and safety recommendations. A five-member board oversees the NTSB and finalizes accident reports. The NTSB has no regulatory or enforcement authority, but it coordinates federal, state, local, and voluntary agency and air-carrier disaster response resources for major airline accidents, as required by the 1996 Aviation Disaster Family Assistance Act. The NTSB performs the same function for major rail passenger accidents involving Amtrak under the Rail Passenger Disaster Family Assistance Act of 2008.

Formal federal aviation accident investigation within the United States originated in the U.S. Department of Commerce under the Air Commerce Act of 1926. The Civil Aeronautics Board Bureau of Aviation Safety assumed responsibility in 1940, serving until Congress established the NTSB as part of the U.S. Department of Transportation (DOT) in 1967. The NTSB was originally housed under the DOT, replacing the older, disjointed, and less effective system where individual agencies separately handled different aspects of the same accident investigation relevant to their jurisdiction or expertise.

Congress designated NTSB independent of the DOT in 1975, under the Independent Safety Board Act of 1974, to strengthen its investigatory capabilities and remove potential conflicts of interest. The federal government further enhanced NTSB objectivity by preventing its involvement in the regulation, enforcement, funding, and direct

A member of a National Transportation Safety Board team inspecting the wreckage of a train car in the aftermath of a derailment in Fairfield, Connecticut, in May 2013.

operation of any of the transportation modes within its oversight.

The five NTSB board members are appointed by the president and serve five-year terms. The president designates two board members as chairman and vice chairman for two-year terms. The Senate must approve the board members, as well as the selection of chairman. The agency houses the following departments: chief financial officer; general counsel; managing director; communications; equal employment opportunity; diversity and inclusion; research and engineering; railroad, pipeline, and hazardous materials investigations; aviation safety; highway safety; marine safety; chief information officer; administration; and administrative law judges. The NTSB comprised approximately 400 employees in 2013.

The NTSB has operated the NTSB Training Center (originally known as the NTSB Academy) within the Ashburn, Virginia, campus of the George Washington University since 2003. The center provides internal employee training and offers transportation disaster response training courses for outside groups, such as emergency responders and local

and state agencies, as part of its mission to improve the coordination of federal, state, and local government resources.

The NTSB's administrative law judges hear appeals to the board from airmen, mechanics, or mariners of certificate actions by the Federal Aviation Administration (FAA) or U.S. Coast Guard Commandant. There are four judges—two based in Washington, D.C.; one based in Arlington, Texas; and one based in Denver, Colorado. The NTSB board members review appeals of the administrative law judges' case decisions.

Accident Investigations

NTSB investigations are centered on a rotational system of Go Teams comprised of various-sized groups of NTSB employees. Go Team members are specialists in fields related to the mode of transportation involved in the accident under investigation. Go Teams are designed for both quick response and a broad array of expertise, both critical factors in successful accident investigations.

The NTSB designates appropriate outside companies or organizations as parties to each investigation. The Federal Aviation Administration (FAA) is automatically designated as a party under the law. Non-NTSB representatives work under the appropriate Go Team specialist and report directly to the NTSB. The party system is cost-effective and allows the NTSB to utilize outside expertise and resources. If criminal activity is determined during the course of the investigation, the NTSB turns lead status in the investigation over to other federal agencies, such as the Federal Bureau of Investigation (FBI), but will remain involved in a supporting role if requested to do so.

A senior-level person, known as Investigator in Charge, coordinates the overall investigation, while each specialist oversees a working group that includes representatives from the relevant outside parties. Various groups within the Go Team remain on site as long as necessary and will travel to other sites deemed relevant to the investigation, such as an aircraft manufacturing plant or maintenance facility.

Aviation accidents tend to have larger investigative teams than accidents involving surface modes of transportation. Aviation specialties may include operations, structures, power plants, systems, air traffic control, weather, human performance,

survival factors, aircraft performance, maintenance records, and eye witnesses. Teams responsible for flight-data and cockpit-voice-recorder analysis meet at the NTSB's Washington, D.C., headquarters, where they are later joined by other team members as their field investigations conclude.

Go Teams are accompanied by an NTSB board member and a public affairs officer, both of whom handle media contact. NTSB policy dictates the release of only factual information and/or safety recommendations to the media and public during the course of an investigation. There is no speculation given as to the causes of an accident. Public hearings involving witness testimony given under oath could be part of major accident investigations.

Publications

The NTSB generates accident reports at the conclusion of each accident investigation. Accident reports encompass detailed factual data and information, as well as analysis and conclusions, including probable accident causation and relevant safety recommendations to prevent similar future accidents. Draft accident reports originate within the Go Team assigned to a particular accident, and board members are responsible for the final report.

The designated chairperson of each investigative group within the Go Team ultimately submits a report on the group's aspect of the accident investigation, which then goes to other groups for verification before becoming part of the public record. Designated outside parties who have assisted in the investigation can also submit their findings for the public record, but they do not aid in NTSB final analysis or reporting. The board prepares the final draft of the accident report and deliberates its findings in a public board meeting. The final report is then published and uploaded to the NTSB Web site.

The NTSB also generates safety recommendations and reports. These could be a result of specific accident investigations or a result of broader safety studies or special investigations conducted separately from accident investigations. The NTSB often issues safety recommendations while an investigation is still active because of the timely importance of safety and the prevention of future accidents. Safety recommendations and reports are placed on the NTSB Web site and are also sent

to any company or agency deemed relevant to the implementation of such recommendations.

Databases

The NTSB and its Web site maintain a number of searchable databases, including its Docket Management System, Aviation Accidents, Safety Recommendation Query, Foreign Investigations, and NTSB Case Decisions database. NTSB reports cover the fields of aviation, highway, marine, pipeline, hazardous materials, and railroad. The NTSB also maintains a "most wanted list" of its top advocacy priorities for enhancing transportation safety. Public safety alerts share designated safety information with the public and encourage citizens to contact state lawmakers regarding these issues.

Regulations governing legal use of reported NTSB findings were put in place to maintain focus on the agency's paramount mission of transportation safety and to avoid any undue influence or conflict of interest. The analysis of data and determination of an accident's probable cause are not admissible as evidence in a court; designated outside investigation team members are not allowed to be put in legal or litigation positions, and limitations are placed on the types of information NTSB employees may testify to in a court case.

Transportation Disaster Assistance Division

Media attention and resulting public criticism over the lack of coordination between the airlines and various agencies involved in large accidents in the past led to the passage of the 1996 Aviation Disaster Family Assistance Act, later followed by the Rail Passenger Disaster Family Assistance Act of 2008. Under these laws, the NTSB is mandated to coordinate federal, state, local, and voluntary agency disaster response resources for major air carrier accidents within the United States and major rail passenger accidents involving Amtrak.

The Aviation Disaster Family Assistance Act covers all commercial aviation accidents involving specified levels of mass fatalities, whether domestic or foreign, within the United States, as well as its territories, possessions, and territorial seas. The NTSB will provide similar coordination for general aviation accidents and accidents involving other modes of transportation upon request, although the agency is not required to provide such services. The NTSB is also not required to provide family

assistance to U.S. citizens involved in overseas aviation accidents.

The NTSB coordinates efforts with the Department of State, Department of Health and Human Services, FBI, Department of Homeland Security, and Department of Defense, as well as the American Red Cross. The Transportation Disaster Assistance Division (TDA) performs this part of the NTSB's mission. Assistance covers a variety of services, including facilitating the availability of information and federal resources to state, local, and voluntary authorities and airlines. The TDA will also share its disaster family assistance knowledge with the transportation industry, as well as both domestic and foreign government agencies upon request.

Service coordination may include such areas as information dissemination, family counseling and crisis counseling support, victim identification and forensic services, personal effects management, memorial services, communication with foreign governments, and translation services. The TDA also manages the Family Assistance Center (FAC), a central space for meeting and service provision for survivors and victims' families typically established by the air carrier involved in the accident under investigation.

Neighborhood Disruption From Highway and Transit Construction and Operations

“Neighborhood disruption” is a broad term most commonly used in transport planning to refer to the various types of economic, social, and environmental disadvantages experienced by a community arising from the implementation of transport projects. Neighborhood disruption is a form of externality. That is, the benefits gained from the transport project are not necessarily shared equitably with the community that experiences disruption related to the transport project. For example, transport projects that are aimed at improving travel times on the transport network could require the bypassing of communities to provide more efficient routes for those traveling.

Changing transport infrastructure inevitably results in a certain level of disruption to neighborhoods. Land use may change. Residents and businesses may be forced to relocate. Travel behavior choices may become restricted or less favorable. The construction process can degrade the neighborhood environment, as well as become a source of inconvenience and disadvantage to those directly impacted. The new infrastructure may act as a barrier restricting previous patterns of movement between people and places.

Although it is unrealistic to expect the elimination of disruption effects from transportation projects, there is also value in trying to understand the community's disruption concerns. Failure to address those concerns can give rise to community resistance to the transport project, which can delay or, worse, threaten the completion of good transport projects.

Neighborhood disruption is not confined to the construction of transport infrastructure but also includes the implementation of transport interventions. Transport interventions such as demand management strategies that change the price, priority, information, or access of transport options have the potential to disrupt individual travel preferences. Increasingly, the disruptive effects of transport interventions are used as an opportunity to

reduce car-dependent travel behavior and encourage use of more sustainable modes of travel. In such cases, the neighborhood disruption might have a greater effect on those who rely on being accessible by vehicle than the people wanting to travel on the new system.

In the context of sustainability, framing neighborhood disruption as a problem per se ignores the fact that disruption events are also desirable preconditions for changing the status quo. Disruption events can be a catalyst for positive change for neighborhoods, such as economic renewal and beautification, and can help shift expectations about and patterns of travel behavior. Disrupting the accessibility of car parking, for example, could be a means to reduce the incentive to drive and to encourage greater use of sustainable mobility alternatives.

Considerations

Transport projects by virtue of their physical structures and long life spans can have long-lasting impacts for a neighborhood. A community's ability to recover from neighborhood disruption can vary. Resilience of neighborhoods to adapt to disruptive change is subject to various factors, such as socioeconomic disadvantage; community cohesion; degradation of environmental assets such as clean air, green space, and ambient noise, as well as economic indicators including property prices, housing affordability, and employment opportunities.

Defining the affected community is important to managing public expectations about the scope of assessments. The neighborhood or community can mean different things to different people. From a pragmatic planning perspective, definitions of a neighborhood are often simplified to mean the people, residents, and businesses within a spatial area, such as a suburb or street.

In contrast, an individual's perspective of a neighborhood is defined by social connections, meaningfulness, and identity, but these are never static. Neighborhoods evolve and neighborhood connections are subject to change in importance. People living outside a spatial neighborhood might have a less intense level of connectivity but could, nevertheless, consider themselves as still having a stake in the neighborhood. Balancing the conflicting perspectives of a neighborhood adds an additional level of complexity for transport planners. Excluding a legitimate section of the neighborhood

from the assessment of impacts is undesirable, but assuming impacts on all neighborhood individuals are equal can distort assessments.

Perceptions of what is an acceptable level of disruption from transport projects vary within the community. At the citywide level, the community might endorse in principle the need to build or enhance transport infrastructure to satisfy the need for fast and efficient connectivity across the city. However, at the microlevel of the neighborhood, the endorsement for such projects varies by the relative exposure to disruption and benefits.

The neighborhoods most affected by disruption are not always the same as the neighborhoods most likely to benefit from the transport infrastructure. For example, transport projects that are designed to increase the speed at which people can travel through the network, such as highways or high-speed transit, could, by design, have limited points of access along the route.

Changes in accessibility are an issue for neighborhood businesses. Accessibility to parking, especially free and plentiful parking, provides businesses with an inherent and comparative locational advantage in attracting customers and remaining competitive. From a business perspective, any reduction in the availability of parking represents a disruption to the norms of doing business. Transport interventions that, therefore, remove parking, even if the objective is to increase sustainable transport options such as transit and cycling, are commonly viewed as threats to business survival.

Businesses will experience economic hardship if they do not adapt easily or in a timely manner to attract customers who are less dependent on car parking. The stresses experienced by the local business community have flow-on impacts to the local neighborhood. If the businesses cannot adapt, the neighborhood business cluster is vulnerable to economic decline, which could ultimately translate to a reduction of local employment and shopping choices. The absence of a thriving local business community providing access to goods (such as fresh and affordable food options), services, and employment is a contributing factor in the relationship between social disadvantage, transport disadvantage, and social exclusion. Assessments of neighborhood disruption, therefore, should also take into account the resilience of the local business community to adapt.

Strategies

Recovery from the disruptive effects of transport projects could be subject to new travel behavior norms being established. In the case of transport projects and interventions designed to increase sustainable mobility options, it could take time for the public to accept and use their new options. For businesses, learning new skills and strategies to adapt to the new environment, so that they can capture value from new mobility options, is important.

Temporary disruptions may be more acceptable than long-term ones to the community, but even the best-planned projects can experience delays. Project delays can test the community's patience and capacity to cope. If the disruptive effects on the neighborhood are long lasting, the community's adaptive capacity needs to be sustained. Taking early action to help businesses adapt to the disruptive effects of transport projects and interventions can help prevent a cycle of decline. Using the disruption events as an opportunity to regenerate and invest in the attractiveness of the business strips and retail precincts, for example, can help generate interest and economic uplift.

Considering neighborhood disruption in the appraisal stage can help identify the context-specific issues that could reduce neighborhood resilience to adapt and benefit from the new transport infrastructure. Sharing information with the community about the opportunities and challenges, and keeping them updated, can help prepare the community for disruption and, where appropriate, alleviate their concerns.

The categorization of neighborhood disruption impacts is not standardized. Reviews of indicators for assessing transport impacts highlight that the overlap between social, environmental, and economic issues at the neighborhood level result in differentiation by context. Neighborhood disruption impacts can be captured under issues of social equity, environmental intrusion effects such as noise and visual impact, interference effects such as barriers to community right-of-way, or economic opportunities.

Economic, social, and environmental impact statements prepared for decision makers can be a useful tool for communicating the merits and trade-offs of a transport project. However, care needs to be taken in using them to communicate about neighborhood disruption. The scale and

scope of issues and measures can be different. For example, macro-level assessments of economic benefits from a transport project, such as travel-time savings, do not easily translate to the micro-level concerns of neighborhood businesses and residents. Likewise, the estimated distribution of benefits ultimately relates to the completion of the project, so they do not reflect the losses experienced by residents or businesses forced to relocate ahead of the project or hardship endured during the construction period. Jurisdictional requirements for impact statements also might vary, but best-practice guides for assessing the localized effects of transport projects can be helpful.

Increasing the sustainability of the transport network is a necessarily disruptive process, because new travel habits need to be formed and inadequate transport links need to be addressed. The willingness of the community to accept the trade-offs will be determined by the value it places on the benefits. Using disruptive events as an opportunity to help the neighborhood adjust might not eradicate the neighborhood disruption, but might help mitigate the longevity and severity of impacts on the area.

Neighborhood Electric Vehicles

Neighborhood electric vehicles (NEVs) are a U.S. regulatory classification of battery-powered electric vehicles that are limited to driving on roads with speed limits of 45 miles per hour (mph) or lower. Many states restrict NEVs even further, usually to roads with a speed limit of 35 mph or lower.

The name refers to the idea of the NEV as a vehicle that can be “driven around the neighborhood,” because, apart from the lack of access to high-speed highways, the battery life will generally not sustain lengthy trips. Most NEVs are similar to the electric cart, which is the most common example and a familiar one from its use both as a security patrol vehicle (such as in malls, parking lots, and college campuses) and a golf cart.

All NEVs are classed by the U.S. Department of Transportation (DOT) as low-speed vehicles. Four states do not allow NEVs on public streets. In a small number of states, most notably California, NEVs can drive on roads with speed limits greater than 45 mph under certain conditions. Legally, an NEV as sold has a maximum speed of 25 mph. The buyer could modify the NEV to achieve a speed of 35 mph, however. Federal safety requirements mandate that NEVs must be equipped with certain basic safety features, including the modern three-point seatbelt, running lights, headlights, brake lights, reflectors, turn signals, and rearview mirrors. Windshield wipers are not required, nor are windshields, or even doors. Some states have additional safety requirements. New York, for example, requires backup lights, speedometers, odometers, a windshield and windshield wipers, and a window defroster.

The crash protection is minimal enough that NEVs are widely considered unsafe for city driving, though they are rarely banned. Further, some have pointed out that the frame of the vehicle and the use of seatbelts makes the NEV safer than bicycles, and the slow maximum speed makes it safer than a motorcycle.

NEVs recharge by plugging into a standard outlet, usually at the owner’s home (or at the place of business where the NEV is used), though there are a small but growing number of electric charging stations in the country as electric vehicles gain support. NEVs do not produce tailpipe emissions and

are classed as zero-emission vehicles in California, making them eligible for rebates offered by that state as an incentive to its residents.

The United States is the largest market for NEVs, with about 15,000 sold in 2011, and about 100,000 in use. The leading manufacturer is Global Electric Motorcars (GEM), a subsidiary of Polaris Industries, formerly owned by Chrysler. Since its first model in 1998, GEM has sold 46,000 of its NEVs. Like most NEVs, GEMs have a range of 30 miles per charge and use a 72-volt battery system that recharges overnight (or in about six hours). Six models are sold, most of them bought by corporate and government agency customers, including university and medical campuses, sports teams, shuttle services, and planned communities. Three of the GEM models are utility vehicles equipped with a flatbed. The utility vehicles and the GEM e2 are two-passenger vehicles. The remaining models

A Global Electric Motorcar (GEM) in service as a police vehicle in downtown Lisbon, Portugal, in 2009. GEMs, made by Polaris, have a 72-volt battery system that takes six hours to charge, and they are able to travel about 30 miles per charge.

are a four-passenger and six-passenger vehicle. The six-passenger is popular as a shuttle service vehicle.

While commercial and government use is the most common use of NEVs, they also have been an important component of certain planned communities, primarily in Florida and California. These communities are designed for slow traffic and minimal need for the frequent long-distance trips commuters in bedroom communities might face. This is true for Celebration, Florida, for instance, a planned community originally developed by the Walt Disney Company, and The Villages, Florida, a retirement planned community. Both were developed with the intention of residents using NEVs for most of their travel needs around the community, and zoning reflects this intention.

In 2011, the Urban Land Institute awarded a Vision Award to Riverside (California) County's Neighborhood Electric Vehicle Plan, which created NEV routes for the four cities of Corona, Norco, Moreno Valley, and Riverside. The plan allows NEVs to be driven on roads with speed limits of up to 55 mph by creating dedicated routes for them, such that their slow speeds neither impede faster traffic nor create a safety hazard. The Riverside plan is considered a model plan of adapting existing communities to encourage NEV use, with minimal infrastructure expenditures.

Other models of NEVs include the following: Blue Sky Design's three-wheeled BugE, which in most configurations is legally classed as a motorcycle because of its 40 mph top speed; the CT&T cZone, from the South Korean company that is the largest manufacturer of battery electric vehicles in the world; AEVCO's Kurrent, which uses four 12-volt batteries and has a 40-mile range; Canadian Electric Vehicles' Might-E Truck, a street-legal utility NEV with regenerative braking and a hydraulic lift; five models of cars and trucks from Miles Electric Vehicles in Los Angeles, sold mainly to universities, the U.S. Navy, and airports; the MIT CityCar designed by the Massachusetts Institute of Technology's Media Lab; and Oka Auto USA's Oka NEV ZEV.

Neotraditional Neighborhoods and Transportation Impacts

Neotraditional neighborhoods are built environments that attempt to apply pedestrian-friendly and multipurpose (for example, employment, residence, and local shopping) neighborhood designs from the pre-automobile era (that is, traditional) to modern, urban, and suburban areas. The ultimate goal is to create what resemble modern urban villages that allow residents to work close to home, partake in local entertainment and shopping, reduce automobile use, and increase walking, while also generating a high level of trust in fellow neighbors and a sense of community.

Neotraditional neighborhoods have increased in number and popularity in recent years. Even though neotraditional neighborhoods have sprouted in Europe and the Southern Hemisphere, these trends have been most pronounced within the United States. Consequently, this entry focuses on the development of this trend in the United States since the 1980s.

Neotraditional neighborhoods have been part of a movement to appropriate "land use" for environmental, health, and community quality-of-life goals. These goals and principles are associated with the movements of "new urbanism" and "smart growth," which are urban development and design strategies geared toward addressing urban sprawl,

suburbanization, greenhouse gas emissions, and other sustainability-related phenomena.

Smart growth and new urbanism strategies contend that the built environment—that is, land use patterns, urban design, and transportation systems—if constructed appropriately, can help protect the environment, curb automobile dependence, and generate sustainable communities, as well as contribute to neighborhood-based development and buffer the effects of urban sprawl on farmland and forest degradation. New urbanists emphasize neighborhood design that is based on traditional urban planning from before the 1950s, hence the term *neotraditional neighborhood*.

A central tenet of new urbanism and neotraditional development is to change travel behavior. A critical aim is to reduce car use and increase transit use and walking.

While results are mixed, research generally affirms the efficacy and effectiveness of neotraditional neighborhoods in fulfilling objectives associated with new urbanism, and, more generally, sustainable development. Studies have consistently shown that the built environment of neotraditional neighborhoods is associated with, and at times directly affects, travel behavior. Even though other factors can explain some of the effect that neotraditional neighborhoods have on their residents—for instance, residents' socioeconomic status or the self-selecting process of individuals choosing to live in neotraditional neighborhoods—the fact remains that the built environment of these neighborhoods can influence transportation. More specifically, residents of neotraditional neighborhoods tend to use cars less, walk more for utilitarian reasons, and use transit more than residents of other types of neighborhoods.

New Urbanism, the Urban Village, and Suburbanization

New urbanism and neotraditional neighborhood principles are embodied by the nonprofit organization called the Congress for the New Urbanism (CNU). As stated on the first page of its 2002 "Charter of New Urbanism," the organization aims to accomplish the following:

[restore] existing urban centers and towns within coherent metropolitan regions, [reconfigure] sprawling suburbs into communities of real neighborhoods and diverse districts,

[conserve] natural environments, and [preserve] our built legacy.

CNU works toward these aims because it views disinvestment in central cities, urban sprawl, racial and economic segregation, environmental deterioration, loss of agricultural land and wildlife, and the lack of attention to cultural heritage as interrelated, community-building challenges.

In essence, New Urbanism proponents advocate a built environment, perhaps nostalgically, that resembles the urban villages of the pre-World War II era. Around the turn of the 20th century, the United States began to urbanize rapidly. This urbanization supported the concentration of economic and social activities within cities' central business districts.

Observing the effects of this urbanization, in the 1930s, Louis Wirth made famous the idea of urbanism, which is understood as a specific way of life that is particular to large, concentrated urban areas. This way of life, according to Wirth, was comprised of new types of social relations, social problems, and less cohesive communities. Even though Wirth's notions became popular, other scholars noted that many urban areas were not characterized by such negative aspects. They observed that within certain urban neighborhoods, residents maintained strong communal ties, interacted on a face-to-face basis, relied on walking and public transportation, and engaged in local shopping and entertainment. In other words, certain neighborhoods tended to resemble "urban villages."

These urban villages, in turn, influenced the perpetuation and preservation of symbolic, historical, and cultural meanings associated with cities and neighborhoods. Therefore, prior to the widespread dispersion of automobiles in the United States, many neighborhoods and cities were built for walking, and streets were designed in a manner that was conducive to social interaction. In addition, local histories and cultures were intertwined with the built environment, and farmland was pervasive and more directly connected to urban centers.

Other processes, particularly urban sprawl, were also beginning to occur prior to World War II, and urban sprawl continues to affect U.S. urban structure today. Because of its frequent use, the term *urban sprawl* can have multiple meanings. For the purpose of this entry, urban sprawl is defined as urban

growth and change characterized by the decentralization and deconcentration of the population and economic activities away from central business districts. In this context, decentralization and deconcentration can also be understood as land urbanization, low-density land use, and suburbanization.

Governmental policies abetted by new transportation and communication technologies contributed to and continue to influence urban sprawl. Most important, the widespread use of automobiles, along with zoning regulations and federal highway construction, influenced urban sprawl. Although many factors feed into urban sprawl, transportation technologies, and specifically, the automobile, are arguably primary catalysts.

As a result of the ubiquity of automobiles in conjunction with other urban development processes, the 1950s marked the greatest period of suburbanization in U.S. history, and by 1990, almost 50 percent of Americans lived in suburbs. This deconcentration, decentralization, suburbanization, low-density land use, and land urbanization remain prominent urban processes, and they have wide-ranging effects. For instance, urban sprawl can affect the environment in multiple and complex ways. Low-density land use has led to the conversion of farmland and forests into built environments, and, as a result, it has exacerbated the extinction and loss of native species, as well as increased greenhouse gas emissions as a result of increased automobile use.

The deconcentration and decentralization of population and economic activity away from central cities has also had a profound effect on the communities and neighborhoods that remain in central cities. Suburban neighborhoods tend to be wealthier and healthier than center-city neighborhoods, and dramatic racial and economic segregation is arguably a prominent side effect.

The urban planning principles associated with neotraditional neighborhoods are a response to these urban dynamics. And, just as transportation influenced sprawl and suburbanization, new urbanists and neotraditional designs aim to alter travel behavior. Put differently, because transportation contributed to urban sprawl and its consequences, neotraditional neighborhoods are designed to impact transportation and make travel behavior more sustainable, thus reducing sprawl and its impact.

Following the logic of “traditional” neighborhoods, new urbanism’s principles pertaining to neighborhood design include the following: neighborhoods and streets should be designed so that citizens interact and are encouraged to contribute to maintenance of the local area; neighborhoods should be dense and mixed use; activities should occur within walking distance, which would increase walking and reduce automobile use; neighborhoods should include housing that facilitates diversity of age, race, and income; and neighborhoods should be oriented around public transit.

Measuring Travel Behavior and the Built Environment

Transportation measures in empirical research on neighborhoods’ influence on travel consist of vehicle miles traveled (VMT), walking behavior, and transit use. Thus, travel behavior consists of at least three modes: auto, transit, and nonmotorized. These three modes are also broken down further by trip length and trip frequency. In addition, there are different forms of travel. For example, there are multiple forms of walking, such as destination walking (that is, travel) as opposed to leisure walking.

Built environment characteristics of neighborhoods that are frequently tested in this line of research can be succinctly summarized by the five “D variables.” These D variables are density, diversity, design, destination accessibility, and distance to transit. The first three—density, diversity, and design—are more frequently studied, but all five are important.

Density is the most frequently studied characteristic, and measures and definitions can be quite different across studies. Measures have included density of population, dwelling units, employment, and building floor area, along with proxies for social and economic characteristics. Diversity commonly refers to the number of different land usages in an area, and high levels of diversity indicate that a neighborhood is a mixed-use environment (that is, employment, entertainment, and housing). Design is understood as street connectivity. Measures can include dense urban grids, sparse suburban streets, and the types and number of intersections. Measures of design tap into the construct of pedestrian-friendly areas versus auto-friendly areas, and so measures have included sidewalk coverage, street trees, and so forth.

Destination accessibility measures the ease of access to trip attractions, such as distance from the central business district. Distance to transit is commonly measured as the average (or some other metric) distance from residential areas or workplaces to the nearest rail station or bus stop in an area.

Transportation Impacts

Do neotraditional developments and their built-environment characteristics influence travel behavior? In general, empirical studies support new urbanism claims. Research for decades has shown that physical, social, and environmental characteristics of neighborhoods influence social lives and behavior, and the impact of neotraditional neighborhoods on transportation is no exception.

Past research demonstrates that residents in neighborhoods with high density, high destination accessibility, mixed land use, and high street connectivity, and that are closer to urban centers, tend to use cars less and walk more compared to residents in suburban neighborhoods characterized by single land use, less accessibility, greater sparseness, less street connectivity, and greater distance from urban centers. However, important differences exist across the different relationships between each specific built-environment characteristic and travel behavior.

As an illustration, while density is the most commonly studied characteristic of neotraditional neighborhoods, its relationship with travel behavior is the most tenuous. In fact, density has the weakest overall relationship with travel behavior compared to all other characteristics. Multiple studies find, for example, that density is associated with the purpose of walking, but not overall walking or physical activity. That is, residents in less dense neighborhoods engage in more leisure walking, while residents in more dense neighborhoods engage in more destination walking (for example, going to the local store).

Of the five major D variables, destination accessibility is most strongly related to travel behavior, including both motorized and nonmotorized travel. In particular, more accessibility is strongly related to fewer vehicle miles traveled. Design measures are also important for travel behavior, but are less important than destination accessibility. Short blocks and more street interconnections can shorten travel distances and increase walking frequency, with intersection density being the most important design measure for walking behavior.

Diversity also plays a role in travel behavior, because creating a good jobs–housing balance and allowing residents to live near where they work induces more frequent walking. Additionally, locating residences near bus stops can lead to more transit use, and nearby transit stops can lead to more frequent walking. Mixed land use can also make it possible for transit users to run errands at transit stops, again reducing automobile use and increasing walking.

It is also important to consider that neotraditional neighborhoods are embedded in a larger urban structure. The regional characteristics of this greater structure have been shown to influence VMT above and beyond the effect of other neighborhood characteristics. In particular, the distance of a neighborhood from the central city is strongly related to VMT. Residents in neighborhoods farther from the center city drive more than their counterparts located closer.

Therefore, factors such as distance from regional shopping centers and central business districts influence automobile use for residents in different types of neighborhoods, regardless of other characteristics of a given neighborhood. Thus, planning strategies that focus on neighborhood development and design need to consider regional characteristics, keeping in mind that regional development is as important for transportation as is local neighborhood design.

Similar to other research on how neighborhoods influence individuals' behavior, self-selection, or the fact that certain individuals choose to live in certain neighborhoods, may explain why the characteristics of neotraditional neighborhoods can impact travel behavior. Research shows that individual characteristics of residents in different neighborhoods influence walking behavior, automobile use, and transit use.

As an illustration, socioeconomic status is associated with travel behavior, because wealthier individuals own more cars and have more choices in terms of travel modes. The number of trips taken and transportation mode choices are influenced by individual-level characteristics, such as socioeconomic status, regardless of the built environment of neotraditional neighborhoods. However, sophisticated statistical analyses have allowed researchers to decipher the difference between neighborhood design effects and the effects of individual-level

characteristics. This allows researchers to examine how neotraditional neighborhoods influence travel behavior while accounting for the fact that certain individuals choose to live in certain neighborhoods. Taken together, this gives a clearer picture of built-environment effects.

Research shows that neighborhood characteristics can influence travel behavior even after accounting for individual differences. In fact, some research has even shown that the effects of the built environment are stronger after accounting for individual-level characteristics, making it clear that individual characteristics are also important to consider. In sum, neotraditional neighborhoods, based on pedestrian-friendly and new urbanism principles, are designed to generate sustainable communities, and they contribute to this end by influencing travel behavior.

Network Modeling

Networks are objects comprised of nodes (also referred to as edges) that are connected by links (also referred to as arcs). This definition is very flexible and can tackle many forms of relationships or connections that define the links. Through this flexibility, it is easy to find networks in many domains.

Historical Background

Network theory is an area of applied mathematics that represents a domain of graph theory. A network model implies an abstraction of reality that helps simplify a problem. Applied mathematics, computer science, engineering, management, and operational research are scientific domains that use network theory.

The beginning of network theory can be traced back to the well-known problem of the seven bridges of Königsberg in Germany. The stated problem was to find a walk through the city that crosses each bridge once and only once. In 1735, Leonhard Euler proved that this was not possible. He reformulated the problem and constructed a network by replacing each landmass with a node and each bridge with an arc. The study of the network led to the identification of valuable properties of the problem and then to its solution, presenting the first steps of network theory.

Because "network modeling" is a general term, developed in many scientific domains, the focus is to analyze the most significant network modeling methods with applications in transportation. In transportation networks, the main objective is to model the objects' movement through the networks. Thus, the most significant work refers to network flow modeling.

This field traces its roots back to 1845, to the work of Gustav Kirchhoff and scientists who first systematically analyzed electrical circuits. However, research on transportation network flow modeling is much more recent. It can be traced to the late 1940s, when the research and practitioner communities simultaneously developed optimization as an independent field of research. Several important network optimization problems related to transportation include the "shortest path" problem, the "traveling salesman" problem, the "vehicle routing" problem, the "multi-commodity flow" problem, the "network design" problem, the "assignment"

problem, the “transportation” problem, and the “minimum spanning tree” problem.

Transportation Flow Modeling Problems

In 1939, Leonid Kantorovich introduced the idea of linear programming. Some years later, in 1951, George Dantzig reinvented and further developed this field. Both researchers’ motivation came from fundamental transportation problems.

The minimum cost flow model is the most general network modeling problem. The problem aims to determine the least costly shipment of goods, in order to satisfy demand at central nodes from available suppliers from other central nodes. The most significant special cases of minimum cost flow problems are the shortest path, the transportation, the transshipment, the assignment, and the maximum flow.

Minimum Cost Flow Problem

First, assume that the problem can be presented by a directed graph $G(N,A)$ where N is the set of n nodes and A is the set of m -directed arcs. Each arc $(i,j) \in A$ has an associated cost $c_{i,j}$, the cost per unit flow on that arc. It is also assumed that the cost varies linearly with the amount of flow. Associating each arc $i,j \in A$ with its upper and lower bounds denotes capacity and minimum amount of flow on the arc.

Each node $i \in N$ is associated with an integer number $b(i)$ representing its supply/demand. If $b_i > 0$, node i is a supply node; if $b_i < 0$, node i is a demand node, and if $b_i = 0$, the node is a transshipment node. The decision variable $x_{i,j}$ represents the arc flows on $i,j \in A$.

The formulation of the linear programming problem can be stated as follows:

$$\begin{aligned} & \min_{(i,j) \in A} c_{i,j} x_{i,j} \\ & \text{Subject to} \\ & \{j:(i,j) \in A\} x_{i,j} - j:j,i \in A x_{j,i} = b_i \text{ for all } i \in N \\ & l_{i,j} \leq x_{i,j} \leq u_{i,j} \text{ for all } (i,j) \in A \\ & \text{Where} \\ & \sum_i b_i = 0 \end{aligned}$$

The first set of constraints guarantees that the total outflows of a node minus the total inflows of a node is equal to its supply/demand. The second set of constraints includes the flow bound of each arc. In order to have a balanced problem, the last

equation, which states that total demand is equal to total supply, needs to be satisfied.

Shortest Path Problem

The shortest path (SP) problem is considered one of the simplest network problems. For this problem, the aim is to find the minimum cost or length from an origin node o to a destination node d , assuming that each arc (i,j) has an associated cost $c_{i,j}$. This basic model has applications in project scheduling, cash flow management, message routing in communication systems, and traffic flow.

The problem can be defined in directed, undirected, or mixed graphs. The problem can also be distinguished from the overall aim if the objective is to find a single pair, single source, or single destination, or even all pairs SP. The literature typically classifies algorithmic approaches for solving SP in two groups: label setting and label correcting. Both approaches are iterative. They assign distance labels to nodes at each step. The two approaches vary in the way they update the distance labels from step to step and in how they converge.

The most significant and well-known SP algorithms are Dijkstra, which solves the single sources versions of the problem; Bellman-Ford, which solves single sources versions even with negative-edge weights; and Floyd-Warshall, which solves all pairs’ SPs. Lately, several heuristics have been developed, aiming to speed up the search by preprocessing techniques. Such algorithms are A^* or ALT algorithm. The linear programming formulation that applies to the shortest path problem can be expressed as follows:

Assuming that $G(V,E)$ is a directed nonnegative graph, and the aim is to find the shortest path from origin node o to destination node d . V is the set of nodes and E is the set of arcs, and $c_{i,j}$ is the cost traveling for each arc $(i,j) \in E$.

The objective function aims to find the path with the minimum cost and, therefore, can be stated as

$$\begin{aligned} & \min_{i,j \in V} c_{i,j} x_{i,j} \\ & \text{Subject to} \\ & j \in V x_{i,j} - j \in V x_{j,i} = 1 \\ & \text{if } i = o - 1 \\ & \text{if } i = d 0 \text{ for all } i \in V \\ & x_{i,j} = 0 \text{ or } 1 \end{aligned}$$

The constraints secure the following three cases:

1. From an origin node, only one node is selected to be visited;
2. only one node is selected to reach the destination node;
3. for all other nodes in the path, there is only one arc that is entering the node and only one arc that is exiting it.

In special cases where the objective is to determine the shortest path from an origin node to all other nodes, then the right part of the inequality is $n - 1$ for $i = d$ and minus 1 for all other nodes.

Transportation Problem

The transportation problem is a special case of the minimum cost flow problem, which is one of the most fundamental of all network flow problems. The aim is to determine a least cost shipment of goods from a set of nodes that represent warehouses to a set of nodes that represent customers, using all alternative distribution channels. The problem is constrained by the restrictions of production of each warehouse and the demand of each customer, as well. Frank Lauren Hitchcock formulated the transportation problem in 1941. At the same time, Tjalling Charles Koopmans also researched the problem, developing the idea of point potentials and an optimality criterion. Because of the initial work of both researchers, the problem is also referred as Hitchcock-Koopmans transportation problem.

However, in 1951, George Dantzig formulated and solved the problem by using the framework of linear programming.

The linear formulation of the transportation problem can be expressed as follows:

Assuming that m warehouses $S_1, S_2, \dots, S_m$ can supply $s_1, s_2, \dots, s_m$ quantities of a product, and that the product has to be transported to n customers $D_1, D_2, \dots, D_n$ that require the following $d_1, d_2, \dots, d_n$ quantity, then the cost for transportation from $S_i \rightarrow D_j$ is expressed by $c_{i,j}$

$$\min z = \sum_{i,j} c_{i,j} x_{i,j}$$

Subject to

$$\sum_j x_{i,j} = s_i \quad \forall i = 1, 2, \dots, m$$

$$\sum_i x_{i,j} = d_j \quad \forall j = 1, 2, \dots, n$$

$$x_{i,j} \geq 0 \quad \forall i, j$$

The first group of constraints guarantees that each warehouse's total outgoing shipment cannot exceed its ability to supply. The second group of constraints states that the incoming shipment of each customer cannot exceed its demand for the product.

In order to have a feasible solution to the problem, it is necessary to make sure total supply is not less than total demand. However, when the total supply is less than total demand, it is still possible to create a balanced transportation problem. This can be established by creating a dummy source and assigning to it a supply equal to the difference between total demand and supply.

Assignment Problem

The assignment problem is a special case of the transportation problem, aiming to identify a perfect match of minimum weight between two equivalent subsets. It was investigated first in 1784 by Gaspard Monge, whose motivation came from the problem of transporting molecules.

In 1912, Jenö (Eugene) Egerváry and Denes König examined it in the framework of matching theory and bipartite graphs. Assuming that $G = (N_1 \cup N_2, A)$ is a weighted bipartite network with $|N_1| = |N_2|$ and $c_{i,j}$ is the arc weight that represents a cost, then the general assignment problem can be stated as the following linear program:

$$\min z = \sum_{i,j \in A} c_{i,j} x_{i,j}$$

Subject to

$$\sum_j x_{i,j} = 1 \quad \text{for all } i \in N_1$$

$$\sum_i x_{i,j} = 1 \quad \text{for all } j \in N_2$$

$$x_{i,j} \geq 0 \quad \text{for all } i, j \in A$$

The assignment problem is also known as the bipartite weighted matching problem. The best-known algorithms that are used to solve the problem are the network simplex algorithm and the Hungarian algorithm. Harold William Kuhn in 1955 explained how the works (from 1931) of two Hungarian mathematicians, Denes König and Jenö (Eugene) Egerváry, had contributed to the invention of his algorithm, named the Hungarian method.

Maximum Flow Problem

The maximum flow problem through a network was initially stated in a report in 1954 by L. R. Ford and D. R. Fulkerson. The problem is stated to be the complementary problem of shortest path. Both

problems seem similar because they both arise as subproblems of the minimum cost flow problem. However, they differ because they capture different aspects of the problem.

In general, the maximum flow problem's aim is to find the path between two nodes in a way to accommodate as much flow as possible, without exceeding the capacity of any arc and mass balance constraints at nodes. In order to formulate the problem, it is necessary to consider a directed capacitated network $G(N,A)$. Each arc is associated with a capacity $u_{i,j}$. To define the maximum flow problem, two special nodes, namely source node s and sink node t , are defined. The problem can then be formulated as follows:

$$\begin{aligned} &\text{max} \quad x \\ &\text{Subject to} \\ &j: i, j \in A, x_{i,j} - j: j, i \in A, x_{j,i} = u \text{ for } i = s, 0 \text{ for all } i \in A - \{s, t\} - u \text{ for } i = t \\ &0 \leq x_{i,j} \leq u_{i,j} \text{ for each } (i,j) \in A \end{aligned}$$

It is noteworthy to state that following the strong duality theorem of linear programming, the "max flow min cut" theorem was derived. The theorem expresses that the maximum value of s - t flow is equal to the minimum capacity over all s - t cuts.

Therefore, the "min cut dual" problem can be formulated as follows:

$$\begin{aligned} &\text{min} \quad \sum_{i,j \in A} c_{i,j} d_{i,j} \\ &\text{Subject to} \\ &d_{i,j} - p_i + p_j \geq 0 \text{ for all } (i,j) \in A \\ &p_s - p_t \geq 1 \\ &p_i \geq 0 \text{ for } i \in A - s \text{ and } t \\ &d_{i,j} \geq 0 \text{ for all } (i,j) \in A \end{aligned}$$

The best-known algorithm for solving the max flow min cut problem is the Ford-Fulkerson algorithm. From the initial directed graph, the residual graph is derived and that the procedure starts with an empty flow. An initial s - t path has to be calculated, and then the flow is updated along the path and the residual graphs until there is no s - t path in the residual graph. The method is based on the augmenting path.

Next Generation Airports, Federal

In engineering and the hard sciences, "next generation" refers to a current or in-development technology that significantly advances a particular application. The process of transitioning federal airports to a group of next generation technologies is sometimes abbreviated as "NextGen." NextGen describes the process of moving to a satellite-based system of air traffic management from a ground-based one. In the context of increasingly scarce resources, intensifying global climate change, and possible terrorist attacks, the Federal Aviation Administration (FAA) has been part of the attempt to delineate the contours of the next generation of airports and of air travel more generally.

The key concept is one of integration of efforts, with a gate-to-gate approach designed to minimize the energy expended by passengers or, from another perspective, to minimize the ability of the paying public to interfere with the smooth running of the operation of air flights. The FAA claims that with careful organization of the different

components of a flight between taxiing to and from the gates, it will be possible to shave seconds or minutes from each individual stage and this, as a whole, will lead to substantial savings in terms of time and efficiency.

The Next Generation Air Transportation System (NGATS) is the new National Airspace System (NAS), implementation of which began in 2012 and is scheduled to continue in stages through 2025. The NAS is the managed aviation system of the United States and the flights and facilities involved. The key aspect of NGATS is transitioning the NAS's air traffic control system from a ground-based system to a satellite-based system, using GPS to allow flights to follow more direct routes and fly closer together. NGATS is designed primarily to decrease air transportation congestion and to save billions of dollars in so doing. The automatic dependent surveillance-broadcast (ADS-B) system that is the cornerstone of NGATS uses GPS transponders to track aircraft positions and broadcast real-time air traffic information to pilots and air traffic controllers. The Next Generation Network-Enabled Weather (NNEW) system reduces weather delays by similarly providing a more complete picture of the weather by gathering real-time information from tens of thousands of sources. Communications are improved through a unified NAS voice switch program, replacing the 17 different voice switching programs previously in use, and the Next Generation Data Communications system that augments voice communication through electronic data communication, reducing air traffic controller workload and reducing distractions while improving information access.

The Joint Planning and Development Office was tasked with overseeing the development of NGATS in 2003, and identified an "agile" air traffic system as one of the key areas in which research and development were needed. Research facilities like the National Aeronautics and Space Administration (NASA) Ames Research Center have worked to meet this need, such as through the development of Cooperative Air Traffic Management (CO-ATM), which improves efficiency and capacity by changing the way tasks are distributed among air traffic controllers on the ground and flight crews in the air. While sector controllers control aircraft on their flight paths, for instance, and area controllers control trajectory changes, controllers

delegate certain tasks to flight crews, like spacing between aircraft. CO-ATM is envisioned as a way to transition from the current system of air traffic management to one in which computer systems handle most air traffic systems while controllers act as supervisors.

The most recent implementation of NGATS is the adoption in August 2013 of the Time-Based Flow Management (TBFM) system in air traffic control centers. TBFM replaced the Traffic Management Advisor system and was developed by Lockheed Martin as part of a 10-year contract awarded in 2010. The new system is expected to reduce delays in airports at greater than 70 percent capacity, and improves trajectory predictions.

It is anticipated that a satellite-based system and enhanced technology will enable the handling of more airplanes than at present, thereby decreasing time spent waiting for takeoff and landing permissions. Because this is a federal-level program, it requires individual airports and their managers to buy into the concept and then to incorporate it in their own facilities. For this to occur, it should be apparent to those airports that the benefits to be obtained outweigh any costs involved.

The FAA's principal approach is to emphasize improvements in efficiency and, hence, cost savings. Better application of science means, for example, that aircraft can be handled in low-visibility conditions through a combination of the Wide Area Augmentation System (WAAS) and the Localizer Performance with Vertical Guidance (LPV), resulting in pilots being able to land their craft with greater efficiency.

The purpose of NextGen as a strategy—which is echoed by comparable efforts in other parts of the developed world—is not change for its own sake but the need to accommodate significant changes in the nature of air transportation in the foreseeable future, as well as to address known problems of efficiency and to modernize systems. Some of these shifts include the enormous increase in budget air travel, the expansion of the flying population with people around the globe who had not previously traveled by air, and the need for greater efficiency in the use of fuel in a world in which the amount of hydrocarbon fuels is rapidly declining and the price of remaining supplies is inexorably rising.

Two other factors have important implications for the efficient management of air space global

climate change and the threat of terrorism. Climate change is becoming increasingly evident in a profusion of extraordinary weather events, which have a major impact on transportation of all sorts. Terrorism has become particularly critical ever since the attacks of September 11, 2001, which featured aircraft as horrifying weapons.

Governments around the world have seized onto the risk of terrorism as a reason for intensifying scrutiny of people within their jurisdictions. Controlling air transportation provides an unusually close interaction between governments' desire for greater control of people's activities and the willingness of the private sector to comply with these requests. There is little doubt that traveling by air these days, particularly in the United States, is significantly less comfortable and enjoyable than it was before September 2001, even though the gains in terms of safety and security are difficult to identify independently. Under these conditions, therefore, there is a need for a new paradigm of customer management in the air transportation industry that is based on security, safety, efficiency, and at least an approach toward sustainability.

Technology and Labor

When new technological applications are introduced into an industry, people working in that industry tend to show some resentment and resistance, resulting from the long history of job losses that has traditionally followed such changes. In the case of skilled or professional labor, such as pilots, there is the additional concern that technology will remove or reduce the intellectual or skilled component of the work, thereby reducing the status of the job and the satisfaction that can be drawn from it. Improving safety standards have already reduced the role of the pilot through the increased use of autopilots, on the basis that controlled flight into terrain—a crash caused by pilot error—is an all-too-common form of air accident. Therefore, discussions on the introduction of changes to be brought about by NextGen will concern the distribution of power between pilots and air traffic controllers, as well as the issue of cost.

In the United States, there are a number of small, independent contractors offering passenger and cargo services. If the FAA is hoping to persuade airport managers to incorporate NextGen technologies across the board, which would be important for

economies of scope and scale to become effective, the agency will need to persuade small operators, too, to compromise their independence of operation and modify their approach. This is not impossible, of course, because people in air transportation are regularly required to cope with significant technological changes.

Consistency Across Borders

Not only is it necessary to ensure consistency of air travel operations across North America, it is also important to have consistency of operations with other countries. Although Europe is an important destination and source of travelers for the United States, preliminary attempts to create interoperability between NextGen and the Single European Sky (SES) program have been shadowed by strikes by French air traffic controllers. The strikers maintain that the attempt to consolidate national-level control schemes into nine international sectors (called functional airspace blocks) is, in reality, an attempt to privatize the service.

The European Commission argues that inefficiencies in the current system add an average of 26 miles (42 kilometers) to each flight. The importance of international norms for safety and procedure was underlined in 2010, when volcanic eruptions in Iceland spewed volcanic ash into the atmosphere, leading to shutdowns of airports all over Europe and stranding millions of passengers. Disputes broke out among airports that disagreed over the need to ground flights. Global climate change incidents that affect weather patterns are also reinforcing the understanding that air travel, like many long-distance activities, requires a transnational approach to problem resolution.

Additional Problems

As a public-sector-led development, NextGen is also bedeviled by the political ideology in the country that argues for the primacy of private-sector operations over public-sector ones, which are characterized as "big government." In spite of such objections, no private-sector organization or consortium has come forward to make the massive investment in research and infrastructure development that the government is making in this context. However, ongoing budget battles make the ongoing support of NextGen, like numerous other government initiatives, somewhat uncertain.

Even if well funded, projects of this scale tend to experience budget growth beyond what is initially anticipated, and so perseverance over the medium- to long term will be important in the context of possible changes of policy under future presidents and Congresses. Already, the program's completion date has been pushed back from 2014 to 2016 and the cost overrun estimates are starting to reach \$500 million.

Problems also have been identified in technology, particularly with the software program at the heart of computerization of the system—En Route Automation Modernization (ERAM)—which exhibited bugs when first put into use. With political discourse about NextGen generally divided along predictable party lines, it remains to be seen whether the program will be implemented as a whole in the format initially envisaged or if reductions will be made. If the project is scaled back, new questions will arise about how the finished model will perform and whether it will ever fulfill its promise.

Nitrogen Oxides

The group of chemicals known as nitrogen oxides (NO_x) are constructed on the molecular level of different numbers of nitrogen and oxygen atoms. The two most common members of this chemical group are nitrogen dioxide (NO_2) and nitric oxide (NO). The nitrogen oxide chemical group is not to be confused with nitrous oxide (N_2O); while nitrous oxide is also a greenhouse gas, it is of a different chemical classification and possesses different chemical properties than nitrogen oxides.

Nitrogen oxides are created by both natural and artificial means. However, although some nitrogen oxides are created naturally, those natural sources are dwarfed by those of artificially created nitrogen oxides. These gases are created naturally by thunderstorms, and created artificially by high-temperature combustion, such as that found in coal-burning engines, petroleum-burning motor vehicles, industrial boilers, and other uses of fossil fuels.

The environmental impacts of these pollutants are significant; they contribute to acid rain, global warming, and other equally serious hazards. The personal health impacts attributed to nitrogen oxides typically manifest in the form of, but are not limited to, ailments of the lungs and respiratory system. Luckily, while the negative implications of this type of pollution are daunting and ever present, there are measures that can be taken on the societal level, the local level, and the personal level to mitigate these effects.

Environmental and Health Impacts

Emissions of nitrogen oxides go nearly hand in hand with the use of fossil fuels as an energy source. These emissions also provide one of the best reasons to curb or eliminate the use of these fuels. The chemical composition of nitrogen oxides allows

them to be easily combined with other pollutants; this can then cause the formation of separate toxic substances. For example, nitrogen oxides could combine with sulfur dioxide to create acid rain, acid fog, acid snow, or harmful dry particulates. Once created, these substances, which are made up of nitrogen oxides and sulfur dioxide, are capable of harming cars, new and historic buildings, bodies of water, and water-dependent ecosystems.

In addition to creating acid rain and similar substances, nitrogen oxides also damage bodies of water via eutrophication, a process that occurs when the atmosphere of a given region possesses an excess of nitrogen oxides. In this situation, the ecosystem attempts to balance the excess nitrogen oxides by absorbing them into available bodies of water. If severe enough, this process may impact the ecosystems contained in those water bodies by changing the chemistry of the water and, in turn, inhibiting the absorption of oxygen into that water. Finally, when water is depleted of oxygen, animal life is unable to flourish, or even survive. This problem has been particularly damaging in the Chesapeake Bay, where the absorption of nitrogen oxides created massive dead zones in the 1970s and 1980s; the bay is still suffering the ill effects of this problem to this day.

Additional harmful effects of nitrogen oxides include global warming and the stunting of plant growth. Nitrogen oxide has been shown to be a greenhouse gas. As such, the introduction of massive quantities of these chemicals into the atmosphere is causing worldwide temperatures to rise. The corresponding increases in temperatures have been proven to be causing glaciers to melt on an unprecedented scale. This melt, in turn, has caused sea levels to rise. While glaciers are not yet completely melted, rising sea levels have already caused the destruction of human settlements and numerous ecosystems. This destruction will only continue unless radical changes are made to the way human society produces energy. The leading cause of nitrogen oxide introduction into the atmosphere is automobile emissions, followed by electrical power plants.

Nitrogen oxides could also cause food shortages in the near future. These substances have been shown to hamper plant growth by inhibiting the plants' metabolic processes. If the plants in question happen to be those that humans grow for food,

A researcher at the U.S. Department of Energy's National Transportation Research Center performs tests on a Mercedes A170 diesel engine, using experimental equipment created to study nitrogen oxide-trapping devices to reduce emissions.

this process then will harm crop yields and diminish food supplies. Furthermore, excess levels of nitrogen oxides in the atmosphere can dim the level of sunlight, which may cause a variety of negative impacts on plant and animal life, including additional reduction in crop yields.

Excessive levels of nitrogen oxides are particularly harmful to susceptible populations, including children, people with lung diseases, and those who work or exercise for prolonged periods. People who are regularly exposed to nitrogen oxides can develop acute respiratory illnesses, such as asthma. Even slightly elevated levels of nitrogen oxides can irritate the lungs of members of these groups or make them more susceptible to infections such as influenza. Higher levels of nitrogen oxides can even harm healthy individuals by causing shortness of breath, collection of fluid in the lungs, burning

spasms, throat swelling, reduced oxygen intake, fluid in the lungs, and even death.

What Is to Be Done?

Despite the grave dangers posed by excess levels of nitrogen oxides, measures can be taken on the large-scale and local levels to curb those dangers. On the national scale, the Environmental Protection Agency (EPA) does regulate nitrogen oxide emissions from power plants and motor vehicles, and limits emissions to those below a level of 0.053 parts per million in the surrounding atmosphere. In addition, because wind patterns can spread air pollutants over vast areas, the EPA has also instituted special regulations for upwind areas so that they do not unduly impact other areas.

There are also a number of measures that individuals can take to reduce nitrogen oxide emissions. Possibly of greatest impact, individuals or families can reduce the amount they drive. Other meaningful measures to reduce nitrogen oxide include the replacement of older, gas-powered appliances with electric ones (preferably fueled by non-carbon-based energy sources) and the cessation of cigarette smoking, which also emits nitrogen oxides.

From a political standpoint, individuals or organizations can support efforts for the development and implementation of renewable power sources, either through activism or electoral methods. Individuals also may take their health into their own hands by limiting their personal exposure to nitrogen oxide; the best way to do this is to avoid living in cities or near highly industrialized areas.

Noise Pollution and Airplanes

Noise pollution is the most frequent source of conflict between an airport and its neighbors. Airport noise is measured and mapped via noise contours and modeled based on runway dimensions and aircraft operations, with extra weight given to nighttime operations. Within the United States, in determining where noise is greatest, the Federal Aviation Administration (FAA) averages aircraft noise over a 24-hour period. This results in a day-night level (DNL) of noise recorded as, for example, 65 DNL. At this level, the average noise is 65 decibels (dB), about the equivalent of a blender or a garbage disposal. Individual events (that is, planes passing overhead) can be over 90 dB, about the level of a rock concert, but when averaged with periods of silence, they result in a more moderate DNL value.

DNL levels are constructed via computer modeling, including data on the mix of aircraft at a particular airport, how noisy those aircraft are, how many operations there are per day, varying climatic conditions, and the altitude of the flight paths. A similar methodology is used in other countries, although the name might be different. In the 1990s, approximately 5 million people across the United States lived inside the 65 DNL. After international restrictions on aircraft noise went into effect in

A noise meter displays a reading of over 86 decibels as an airplane passes over Neptune Road in Boston, Massachusetts, near Logan Airport, in 1973. In the 1960s, local communities began to advocate for noise reduction and noise standards to benefit those living near airports.

1999, that number dropped to 323,000 people, although this does not mean that quality of life or property values rebounded in value. At the same time, the noise level may be offset for some residents by increased accessibility to jobs. The consistency of the effects of airport noise on property values over three decades of study, even as jet aircraft have gotten quieter, is noteworthy.

There are two main sources of noise from an aircraft: drag or resistance around the various parts of a plane, and the engine. First, the airframe itself introduces a certain amount of noise, particularly as flaps, slats, and wheels are deployed for landing to increase the surface area exposed to the air. Studies have found that once the landing gear has been deployed, the noise experienced on the ground can increase by up to 10 decibels (dB). Because of the logarithmic scale of decibels, this is equivalent to a doubling of noise.

Generally speaking, any improvements to the airframe that reduce noise do so by enhancing the

aerodynamics of the plane. Such improvements are therefore attractive to airlines seeking to reduce fuel costs and are not likely to be controversial.

The greatest contributor to aircraft noise, however, is the engine. Simply put, a jet engine works by pulling in air through a fan and then compressing that air through a series of smaller-bladed fans until it is dense and highly flammable. When jet fuel is introduced into the compressed air and burned, the rapidly expanding air is forced out the back of the engine (and turning turbines that make the fans rotate), propelling the engine and, thus, the aircraft forward. The fans generate considerable amounts of noise, as does the exhaust coming out of the engine.

Engine noise dominates on takeoff and while cruising, whereas noise from the airframe may actually be most noticeable upon landing. Many measures to reduce noise can enhance engine efficiency. For example, one of the major jet engine improvements of the 1970s, the high-bypass turbofan engine, lets most of the air that it pulls in flow around the compression and combustion areas rather than through them, providing some insulation from the noise being generated within. However, some noise improvements can actually increase drag and slow the plane down, making them less likely to be adopted by aircraft manufacturers.

While propeller-driven engines are not entirely quiet, there was a significant jump in noise when propeller planes started to be replaced with the first jets in the 1960s. Pressure from local communities and governments led to the introduction of noise certification in the United States in 1968 through the Aircraft Noise Abatement Act. This meant that aircraft manufacturers had to meet noise standards before their planes could be allowed into service, the same way they already had to meet safety standards.

International multilateral agreements resulted in significant noise reductions in 1988 and again in 1999. In contrast to the noise measurement of the DNL, which is averaged over a period of time, these standards were based on one-time measurements of noise as experienced upon takeoff and landing as an aircraft flew overhead, as well as a measurement to the side of the plane on takeoff. Aircraft that did not meet the noise restrictions had to be completely replaced (obviously, an expensive proposition); have their engines replaced; or have

a “hush-kit,” similar to a muffler, fitted over their engines in order to meet the new noise limits. Different airlines chose different solutions, resulting in significant variation in noise levels from airline to airline and even airplane to airplane.

Beyond changes to the aircraft, airports have introduced a number of techniques to reduce the noise experienced by those on the ground. Early restrictions included upper limits on the weight of aircraft, which increased the rate at which planes could climb but reduced airline revenue in the process.

One of the most common techniques used by airports today is preferential runway usage. When wind conditions permit, runways that point over more densely populated areas are avoided by air traffic control in favor of those aimed at open space or industrial areas. Similarly, flight tracks for arrival or departure may be modified to either concentrate noise over compatible uses or spread it out over incompatible areas. This can be seen at Minneapolis–St. Paul International Airport, where aircraft taking off to the southwest are directed to maintain a constant heading that keeps them over industrial land, while aircraft taking off in the reverse direction are given slightly different headings from one another to distribute the noise more broadly over a heavily residential area.

Beyond the route an aircraft takes, pilots may also be directed to reduce the initial thrust of their aircraft until they have reached a suitable altitude. At some airports, such as O'Hare International in Chicago, community organizations have met directly with air traffic control staff and pilots to persuade them to use preferential runways and/or flight tracks.

Aircraft also generate noise on the ground, whether on the runways and taxiways or elsewhere. This noise can be abated in three main ways: relying more on braking and less on reverse-thrust engines to slow the aircraft once it has touched down; doing maintenance tests of engines only during regular airport operating hours, rather than in the late night or early morning; and using ground vehicles to push back from gates and taxi the plane, rather than relying on aircraft engines.

Low-frequency noise can also be an issue in locations parallel to the runway. This noise is more like a vibration than an audible sound, and it has not been shown to create the same levels of annoyance among nearby residents as more direct aircraft noise. Nevertheless, it is not included within

airport noise models, and, therefore, individual airports may have to deal with abatement or mitigation issues brought forward by their neighbors.

New noise management techniques continue to be developed. For example, aircraft are typically directed to descend into an airport in a series of steps, alternating between descent and level flying. This requires the use of flaps and slats on descent and occasional engine thrust to maintain altitude, both of which contribute to increased noise. The newly piloted continuous descent approach, as its name implies, brings aircraft in on a steady descent, which produces less noise than the traditional stair-step approach, especially for communities seven to 15 miles from the airport. This approach has been developed in the United Kingdom, and it is beginning to be tried elsewhere in Europe, with the potential of being tested in the United States in the future.

Although aircraft noise levels continue to decrease in response to regulation and innovation, noise continues to be a significant environmental problem for airport neighbors and, thus, an issue of concern to the global air travel system.

Noise Pollution and Cars

Though not as frequently discussed as local air pollution or the transport sector's contribution to climate change, noise pollution constitutes one of the major social and environmental costs associated with traffic. This entry explains the nature of noise and how it is measured, summarizes factors determining the level of noise created on roads, and describes the main health effects of noise. The main regulations that address road traffic noise and its reduction in the United States and the European Union (EU) are mentioned. Noise abatement and noise from railways and aviation are not covered.

The Nature of Noise and How It Is Measured

Sound pressure from road traffic is measured in decibel A, or dB(A), which quantifies a logarithmic rather than linear scale. For example, 70 dB(A), about the average daytime sound pressure at the edge of a main road, is twice as loud as 60 dB(A), about the equivalent of a lively conversation. However, the actual definition of noise is highly subjective, and people generally consider any undesirable sound to be noise, irrespective of the dB(A). The threshold at which humans begin to experience physical pain lies at around 120 dB(A), reached or exceeded by the sound system at a rock concert or a referee's whistle, for example.

Noise is different from other vehicle emissions in that it is present only while its source is, so it must be quantified differently from other types of pollution. An equivalent sound level or L_{eq} is generally used to quantify community sound levels and to describe and compare noise at different time periods and locations. L_{eq} is constructed by averaging the total acoustic energy contained in the varying sound pressure levels measured over a certain period of time and denoting the L_{eq} as the dB(A) value equivalent to this average sound pressure. For example, $L_{eq}(h)$ describes the sound level equivalent that is reached during the noisiest hour of a day. This unit is commonly used in the United States for quantifying and regulating traffic noise.

The L_{eq} most frequently used in the EU are L_{night} for an eight-hour nighttime period, and L_{den} for a 24-hour period (day-evening-night). Weighting is applied to the evening and night components of L_{den} to account for the fact that the same sound levels are perceived as more disruptive in hours typically

devoted to resting or sleeping. The averaging carried out to create an L_{eq} can mask very different sound profiles, however. Several loud single sound incidents interspersed with quiet periods can result in the same L_{eq} value as more continuous but intermediate sound levels observed over the same time span, even though they would have different effects on sleep, for example.

Traffic noise is more often modeled than measured. This is a necessity if future noise levels need to be predicted, such as those associated with a planned road building project. Modeling is also generally used when existing noise levels need to be quantified for larger areas or over an entire road network. The resulting L_{eq} relate to outdoor environments, normally referencing a particular vertical and horizontal distance away from a road's center line. The actual noise levels experienced by people will diverge from the modeled L_{eq} , but using a standardized value allows meaningful comparison of traffic noise at different locations, or at the same locations but different points in time.

Noise From Road Traffic

Vehicle engine size and technology have a strong influence on traffic noise levels. However, when speeds of around 25 miles per hour (40 kilometers per hour) are exceeded, noise created by the aerodynamic drag of the vehicle and by tire friction on the road surface become louder than the engine sound. Road surface quality also influences sound levels; a smooth but porous surface is more effective at absorbing sound than a less porous and/or uneven surface.

Volume and composition of traffic also play an important role in determining sound levels. A single heavy-duty vehicle may generate a noise level equivalent to about 40 passenger cars. Increasing traffic volumes create higher sound levels, but changes in these metrics are relative to the ratio of traffic levels that are compared. Removing 2,000 vehicles from a road previously used by 4,000 vehicles per day decreases the L_{eq} for that road by a greater dB(A) value than adding the same 2,000 vehicles will increase the L_{eq} from a road previously used by 10,000 vehicles.

Because of the noise generated by braking and accelerating, vehicles traveling at varying speeds generate more noise than the same number of vehicles in smoothly flowing traffic, even if the average

speed remains constant. The cross-sectional profile of roads and adjacent buildings play a further role. Wider streets flanked by low buildings, possibly even with gaps in between (alleys, parking lots, etc.), lead to less reflected noise than narrow street canyons with closed frontages. However, the traffic noise audible behind such closed building fronts will be much lower than behind discontinuous structures.

The noise levels reaching individual receptors (that is, people) depend on their distance from the source—sound levels decrease proportionally to the square of the distance—and any barriers between them and the vehicles. These can include noise barriers along highways, vegetation, and buildings. It has even been shown that the same sound level is evaluated less negatively by people when its source cannot be seen. The noise level that is objectively created inside a building by traffic outside depends on the quality of the walls and windows, ventilation systems, and the acoustic properties of the rooms.

Health Effects of Noise

Noise levels above 120 dB(A) can cause acute pain, as well as temporary auditory impairments and even permanent hearing damage. At night, noise levels of around 40dB(A) generated by road traffic can cause sleep disturbance with associated short- and long-term effects, such as fatigue, deterioration in cognitive functions, and chronic disruption of sleep patterns.

Lower-level noise is also considered a nonspecific stressor, which results in adverse health impacts through the body's physical stress responses. These are partly determined genetically but are also modified by experience and environmental parameters, and, thus, have an important subjective element. The same measured sound levels can be differently perceived by different individuals, inducing different stress responses depending on the subject's evaluation of it (for example, music, construction noise, or the neighbor's leaf blower).

Physiological responses to noise stress include changes in blood pressure and heart rate, and increased release of stress hormones. Over prolonged periods of time, such stress responses can cause permanent functional changes in the body that are considered to be cardiovascular risk factors. Chronic noise stress is thought to be associated with an increased risk of hypertension (high

blood pressure) and ischemic heart disease, which is caused by reduced blood supply to the heart muscle. In 2011, the World Health Organization estimated that 800,000 disability-adjusted life years (DALYs), which are years that would otherwise have been lived healthily, are lost every year in the EU as a result of sleep disturbance caused by traffic noise.

Regulations Relating to Road Noise

The U.S. Code of Federal Regulations Part 772 details "Procedures for Abatement of Highway Traffic Noise and Construction Noise," which apply to all new highways, alterations to highways, or noise-abatement projects receiving federal aid or approval. The Federal Highway Administration's associated "Noise Abatement Criteria" define different noise levels that are acceptable for different types of land uses. For example, 67 dB(A) L_{eq} is allowed for residential areas, and 72 dB(A) around hotels, offices, and restaurants. It is important to realize that these limits only need to be considered in the planning of projects defined above. They do not need to take into account noise from other sources.

The EU's Environmental Noise Directive (2002/49/EC) stipulated that by mid-2013, strategic noise maps and related action plans were to be drawn up for agglomerations with more than 100,000 inhabitants, major roads used by more than 3 million vehicles per year, and major railway lines with more than 30,000 train passengers per year. These maps and plans must show the status quo and be reviewed every five years or when there is a new major development. Communities must take remedial action if certain L_{den} or L_{night} dB(A) values are exceeded.

The EU directive does not define these limits, though. It was left up to the member states to decide on them, a task that in some cases was delegated to the local planning authorities. In Germany, for example, the most commonly set upper acceptable thresholds are 54 dB(A) for L_{night} and 64 dB(A) for L_{den} . The EU directive also regulates comparable measures for noise from railways, airports, and industry, but the possible combined effects of these sources need not be considered together. Multiple exposures could therefore result in legal limits being breached without any official requirement for abatement measures.

Noncommuter Travel

Noncommuter travel is travel for purposes other than going to work, such as for shopping or other household errands transporting children to and from school or activities (or in the case of older children, their transport of themselves); attending church and going to the gym; appointments with doctors, dentists, and salons; visiting family; and recreation.

These are rich areas for research, because while workers may have limited choices in terms of commuting travel behavior—beyond choosing a job, and choosing between different modes of travel such as driving alone, carpooling, walking, or using public transportation—people have much more control over their noncommuting travel behavior. This has especially been an area of interest since the 1960s or so, as the country became deeply suburbanized, reversing the century-old trend of increasing urbanization and creating a larger and larger populace dependent on driving.

For instance, a 2001 study of shopping patterns in Austin, Texas, found that drivers frequently chose more distant shopping destinations even when options local to their neighborhood were available to them. The study investigated the effectiveness of the frequent proposal that "urban-style" development planning, with decentralized commercial districts so that suburban neighborhoods have more

local shopping options, was a solution to suburban automobile overuse and overdependence. This study suggested that this solution would be ineffective, as factors other than distance and whether or not a car was needed impacted shoppers' choices. While consumers have experienced more fuel price volatility since that study, "big box" stores offering lower prices at the outskirts of town have become even more common.

This tendency to rely on cars even for shorter distance trips has been confirmed by the National Household Travel Survey (NHTS), which found in 2009 (the most recent survey) that 60 percent of trips under one mile were made by automobile. In many instances there may be little option but to drive even for such short trips—as some advocacy groups for greener travel have noted, not everyone has equal access to walking and bicycling, due to neighborhood layouts, safety features or lack thereof, and the presence or absence of sidewalks, paved shoulders, crosswalks, bike lanes, and bicycle storage facilities.

The growing interest in noncommute travel is reflected in the most recent NHTS survey, which added new questions pertaining to online purchases of delivered goods (which have a travel impact if they reduce shopping trips) and noncommuting employment-related travel, such as work-related travel for self-employed workers (the driving done by a self-employed plumber to a work site, for instance, or a craftsperson trips to pick up supplies and mail items).

Compared to the previous survey in 2001, the overall number of trips per driver and total vehicle miles both decreased slightly. These decreases were seen across various categories of noncommute trips. Social and recreational trips fell from 441 trips and 5,186 miles (annually) in 2001 to 436 trips and 4,842 miles in 2009 and "other" (which includes trips to church and to transport children) trips fell from 537 trips to 500, and 3,956 miles to 3,515 miles. While shopping-related vehicle miles fell from 3,062 to 2,979, shopping-related trips grew slightly from 459 to 468, though that amount is within the margin of error.

Travel was strongly correlated to income, though increases in noncommuting travel level off in the highest income brackets. More noncommuting travel is conducted by women than men, and the reverse is also true, though trips for school, church,

and recreation are roughly gender equal. The main difference is in family- and shopping-related trips, from picking children up at school, activities, or friends' houses, to taking them to the doctor or to have their hair cut, all of which types of travel are pronouncedly female dominated. The prevalence of women over men making family and shopping-related trips is the same as that of men over women for commuting trips, about 25 percent.

When broken down into destinations, "home" was the most popular (as it would need to be, as the endpoint for most return trips), while "shopping for groceries, clothes, or at the hardware store" was the only other destination to occur more frequently than the workplace. The next most popular destination, eating out, was less than half as common as the workplace.

In order of declining popularity, the remainder were dropping someone off, picking someone up, visiting friends or relatives, services (dry cleaner, post office, car service, bank), noncommuting work-related, gas station, other forms of shopping, the gym or sports, medical or dental services, church or religious activity, entertainment (including movie theaters, spectator sports, and bars), personal business/obligations, attending school, coffee/ice cream/snacks, unspecified social or recreational purpose, vacation or relaxation, nonwork meetings (homeowners associations, local government, PTA), personal services (hair, nails, salons), professional services (lawyers, accountants, tax prep), visiting public places like museums or libraries, pet-related trips, funerals and weddings, school-related library trips, and day care.

Though efforts have been made to increase participation in car pooling and to extend public transit coverage, the dominance of automobiles over other modes of travel for noncommuter purposes has been unchanged since 1990. The majority of public transit trips are work related, and driving accounted for 88.5 percent of all trips made in 2009, with walking a distant second.

But some cities have begun actively trying to change their residents' noncommuter travel behavior in ways other than just offering car pooling incentives. For instance, since the 1990s Portland, Oregon, has worked to expand the bikeability of the city by paving more shoulders and adding more bike lanes, and from 1991 to 2008 increased the bikeway miles of the city from 75

to 275. Ridership increased fivefold in the same period and has continued to increase since. Boulder, Colorado, has also worked to reduce car usage in the city by paving street shoulders and increasing sidewalk coverage (to increase pedestrian and bicycle travel), adding 380 miles of dedicated bike lanes or trails, and expanding and improving its public transit network. From 1990 to 2006, public transit trips nearly doubled, while driving declined and walking and bicycling increased.

In 2011, Boulder launched its bike-share program, with 100 bicycles distributed among a dozen bike-share stations. Users are allowed to purchase an annual, seven-day, or 24-hour pass for the program (available from kiosks publicly accessible 24 hours a day), entitling them to use a bicycle for up to one hour at a time for no additional fee. Additional fees accrue after that in order to encourage fast turnover.

The bicycle program is intended to be used less for recreational biking and more to replace other travel options, particularly car use. The flexibility of bicycling also frees some consumers from the necessity of car ownership, even if they live in an apartment or condominium without facilities to store their own bicycle. Bicycle and pedestrian travel are more likely in neighborhoods with "complete streets"—streets designed to accommodate all the forms of travel in their neighborhood, which means bicycle lanes or paved shoulders, sufficiently large and well-maintained sidewalks, frequent safe crossing opportunities, and, ideally, dedicated lanes for special vehicles such as buses in urban areas or tractors (which are wide and slow-moving enough to impede bike and foot traffic) in farming communities.

Nonmotorized Transportation

In many developed countries, walking and bicycling are not extensively used as a means of transportation, mainly attributable to societal attitudes toward walking and bicycling, sprawling development patterns, increased trip-chaining behavior, traffic safety and personal security considerations, and longer distances between residential locations and activity-participation locations.

Even in developing countries, where the nonmotorized share of trips has traditionally been much higher than in developed countries, there is a general trend of nonmotorized trips decreasing in share as a result of economic growth, the increased ability to purchase and use motorized vehicles, increasingly nonmixed land use patterns, and motorized vehicle ownership being viewed as a symbol of status and wealth.

The net result has been increasing urban traffic congestion in both developed and developing countries, with the concomitant consequences of air quality degradation, more inactivity and sedentary lifestyles in the population, and rapidly increasing greenhouse gas emissions with associated climate change effects. Projections suggest that the situation will only worsen over time unless sustainable

transportation options, such as the use of nonmotorized travel modes, becomes more prevalent.

In addition to planning and transportation professionals, the topic of nonmotorized travel, also referred to as "active transport," is gaining attention from health agencies. This is because physically inactive lifestyles pose significant health hazards. Specifically, insufficient physical activity has been identified as being among the leading causes of death and disability in the world. It is a serious risk factor for chronic physical and emotional diseases (such as coronary heart disease, stroke, some cancers, diabetes, and depression), which are among the leading causes of mortality. In addressing these health problems, health agencies around the world have identified active transport as a pivotal means to boost the levels of physical activity among individuals.

The societal problems associated with increasing motorized vehicle use and decreasing nonmotorized mode use has led many local, regional, state, national, and even international agencies to consider strategies to increase nonmotorized travel. At the same time, because the resources for funding transportation improvements are limited, planners and policy makers need to assess the potential usage and benefits of improvements in nonmotorized transportation against alternative transportation projects.

Such assessments require a good understanding of nonmotorized travel behavior to estimate the impact of policy actions aimed at encouraging bicycle and pedestrian travel. In contrast, evaluating the effects of bicycle and pedestrian infrastructure and programs on travel behavior and emissions is, in general, not (yet) a well-developed science. In particular, there is a need to identify and conceptualize the deterrents to nonmotorized mode use within the different contexts of developed and developing countries, as well as to pursue analyses to isolate and quantify the effects of these deterrents and corresponding countermeasures.

Challenges and Benefits

The deterrents to nonmotorized mode use in developed countries are generally assumed to include long trip distances resulting from sprawling land use patterns, increased trip chaining in a single sojourn from home or work, vulnerability to injury in the event of a crash with a vehicle, vulnerability to crime (an issue found particularly to

influence parents' decisions to allow their children to walk or bicycle to school), lack of shower and locker facilities at the workplace, a social perception that nonmotorized modes are uncomfortable or taxing, and a general social stigma against anything other than car use. The increasing deterrents to nonmotorized mode use in developing countries include the same considerations as those for developed countries, along with relatively poor nonmotorized mode infrastructure facilities.

Strategies to promote nonmotorized modes must address these deterrents, while also emphasizing the positive benefits of nonmotorized mode use at the personal level (such as better mental and physical health), the family level (potentially, lessened transportation expenditures and medical expenses, and more contact time with children and/or other family members), and society as a whole (less traffic

congestion and more social vibrancy). In particular, information campaigns can be an effective method of encouraging nonmotorized transportation and creating a culture of walking and bicycling.

For example, the GetAbout Columbia project in Columbia, Missouri, increased the proportion of residents who agree that the city is pedestrian- and bicycle-friendly from 66 percent to 80 percent in three years. Such attitudinal and perception changes can be important to shifting travel behavior.

There also are a number of other promising ways to achieve the numerous benefits of nonmotorized transportation throughout both the developing and developed world. A variety of policy tools are available to planners and governments facing environmental and mobility-related challenges.

In developed countries, pricing strategies such as London's congestion charge can be effective in reducing automotive travel in city centers and encouraging residents to use a combination of nonmotorized and public transit options. In addition to such "sticks" to discourage the use of personal motorized forms of travel, "carrots" can be offered for the use of nonmotorized modes in the form of subsidies associated with public transportation use and/or health insurance premium reductions based on the amount of nonmotorized mode use.

In developing countries, promoting nonmotorized travel over the personal automobile will require an attempt to challenge the widely held view that owning a car equates to personal success and freedom. Local authorities everywhere can develop more dense, mixed-use developments, which can encourage nonmotorized travel and promote more active lifestyles.

It is also critical that researchers continue to investigate factors that affect nonmotorized-travel behavior and the effectiveness of associated policies. As policy makers work to integrate nonmotorized travel into their transportation systems and planners pay more attention to the effects of land use on travel behavior, researchers must continue to investigate how, why, and to what extent these new policies are effective in providing safe and reliable transportation to all travelers.

In addition to evaluating existing policies, research should also investigate new possible avenues for facilitating nonmotorized travel, thus providing innovative solutions to both old and new transportation problems. As always, studies must

A horse-drawn vehicle is a mechanized piece of equipment with either two or four wheels pulled by one or more horses. In developing nations like India, horses, llamas, oxen, donkeys, and even dogs remain important modes of transport.

explore the effects of transportation policies on the health and safety of both the public and the environment.

As countries, cities, and towns throughout the world work toward improving the way their transportation systems serve their residents, promoting nonmotorized travel presents an attractive option to relieve congestion, improve public health, and reduce emissions of pollutants.

Nonmotorized Vehicles, Safety Issues of

Nonmotorized vehicles are vulnerable to a broad array of hazards to which motorized vehicles are not generally susceptible. Safety issues for users of nonmotorized vehicles fall into several different areas of concern. These include behavior, infrastructure, education, enforcement, and the physics of reducing injury and death. This entry also addresses hazards, vulnerabilities, and some methods to improve safety.

Definitions

Several definitions are pertinent to the issue of safety in relation to nonmotorized vehicles:

Nonmotorized vehicles. These are vehicles that are powered by human energy, including bicycles, unicycles, tricycles, scooters, skateboards, roller skates, inline skates, roller skis, wheelchairs, and other human-powered vehicles. It is important to note that while their devices are not classified as nonmotorized vehicles, users of motorized wheelchairs, mobility scooters, electric-assist bicycles, and various gas-powered scooters and skateboards often share the same challenges that nonmotorized vehicle users experience in regard to limited facilities and vulnerabilities to larger, heavier, and faster vehicles.

Active safety measures. These are actions taken to protect nonmotorists. While traveling on a nonmotorized vehicle, the following principles are essential elements of crash prevention: control the vehicle, follow the rules of the road and know traffic law, be visible, be predictable, use good lane positioning, signal your intentions, pay close attention to other road users and road hazards, learn to watch for and avoid other drivers' mistakes, and allow buffers of space in all directions for slowing, stopping, and maneuvering.

Collision. A collision is an impact caused by two or more moving vehicles or bodies coming into contact and exerting force upon each other.

Crash. When a bicycle rider loses control and impacts a stationary object or falls from the bicycle. A collision is a type of a crash, but not all crashes are collisions.

Nonmotorist. This is the user of a nonmotorized vehicle.

Passive safety measures. These are not actions per se but include protective equipment such as helmets, gloves, wrist guards, pads, body armor, and eye protection.

Rights and Responsibilities of Operators

In the United States, bicycle riders are differentiated legally from users of other nonmotorized vehicles in that they are classified as vehicle

operators. So, they are granted all the rights and responsibilities of drivers of motorized vehicles when they travel on roadways. In all 50 U.S. states and the District of Columbia, bicycles are either (1) defined as vehicles or (2) granted all the general rights and duties of drivers of vehicles when they are traveling on roadways.

It is important to be familiar with the legal rights and responsibilities of all road users in the locales where one travels. In addition to bicycles, other nonmotorized vehicles may be regulated by state, county, or local jurisdictions. It is best to check your state and local laws and to be familiar with your rights and responsibilities as a nonmotorist. In some jurisdictions, nonmotorized vehicles may be restricted to sidewalk use (requiring slow-speed travel and yielding to pedestrians), restricted from sidewalk use, banned altogether, or left unregulated.

While bicycles are often clearly regulated and may have dedicated facilities, other nonmotorized vehicles may face a greater legal and practical ambiguity when it comes to defining safe operation. This ambiguity is itself a hazard; if nonmotorists do not understand their role in traffic, risky behaviors are more likely. This is not an exhaustive treatment of nonmotorists' vulnerabilities, but one of the most common hazards and vulnerabilities of nonmotorists is that of speeding motor vehicles.

Education and Enforcement

Many nonmotorized road users are not aware of the laws that apply to them; nor are they aware of the legal rights and responsibilities of other road users. Many risky behaviors on the part of all classes of road users have become normalized; these commonly include speeding, failure to yield, and failure to stop. To improve the safety practices

A woman and child transport multiple bags and packages in New York City's Central Park while using two different types of nonmotorized vehicles: a bicycle and a kick scooter. Helmets, gloves, eye protection, and pads are recommended for users of nonmotorized vehicles, which may have additional vulnerabilities because of small wheels and a lack of brakes.

of road users requires the education of all users about their rights and responsibilities, as well as the impacts of risky behaviors. Education is best supported by a visible increase in even-handed enforcement practices.

Effects of Changing Technology

Electric and hybrid cars present special threats to nonmotorized travelers because they are so much quieter than automobiles powered solely by internal combustion engines. Users of nonmotorized vehicles rely heavily on their hearing, and the lack of engine noise of hybrid and electric cars make it more difficult to hear an approaching vehicle.

Higher collision rates between hybrid cars and bicycles have been observed than between bicycles and conventional autos. Although one study only looked at bicycle collisions, this is a hazard for all nonmotorized modes of travel, including walking.

Hazards

There are many dangers to nonmotorists, both stationary and moving hazards. Stationary hazards include broken pavement, potholes and longitudinal seams in the road surface; metal fixtures in the roadway (for example, drain grates and manhole covers); debris such as broken glass, sand, gravel, pavement chunks, tire retreads, litter, and leaves; fragmented networks of facilities for users of nonmotorized vehicles; and confusing and inadequate facilities, which may inspire risky behavior.

Moving hazards can include speeding, aggressive, distracted, and inattentive road users of all modes (including other nonmotorists); dogs and other animals; pedestrians; and doors opening from stationary vehicles. Stationary hazards can be relatively easy to avoid, while moving hazards can be more challenging. This is only a partial list, and there are often additional hazards that are locally specific.

Each of these hazards, combined with the nonmotorists' own vulnerabilities or weaknesses, poses risks to the individual rider of a nonmotorized vehicle. The nonmotorist can employ many practices, however, to reduce that risk. For example, riders are only vulnerable to the hazard of the door zone if they ride there.

Riding skills, along with equipment type and condition, play a big part in the performance of a nonmotorist in relation to hazards and rough

conditions. A rider's accurate self-assessment of skill and equipment is also of crucial importance to safe operation of any vehicle, but especially a nonmotorized vehicle.

Critical thinking, good judgment, and experience each contribute to safe operation. If conditions are especially hazardous, it is best to slow down, stop, or find a different route. While it is important to know the relevant legal frameworks where and when one rides, prudence dictates that nonmotorists err on the side of being conservative; having a legal right on a road does not mean that a person will be able to survive a hazardous situation unscathed.

Vulnerabilities

Nonmotorists have many vulnerabilities, some that are particular to the specific mode and some that are general. Generally, nonmotorists are vulnerable in that they are not enclosed within their vehicle, making them as exposed as a pedestrian, even though they may travel much faster than pedestrian speed. Nonmotorists are generally not well accommodated, expected, or respected on the roadway, and they tend to move more slowly than motorized vehicles. As with any travel mode, nonmotorists are sometimes unable to control their vehicle, and they fall or crash. Learning to control one's vehicle and safely maneuver it is the foundation of active safety, and a way to reduce or eliminate operator-caused crashes.

The particular vulnerabilities of nonmotorized vehicles are largely based on the wheel size and type, as well as the inclusion, or not, of brakes. Except for bicycles, nonmotorized vehicles generally have small-diameter wheels. Smaller wheels have a more difficult time rolling over obstacles than a larger wheel would have rolling over the same obstacle. Potholes, curbs, gutters, drain grates, manhole covers, and other road hazards present greater danger to smaller-wheeled vehicles than to their larger-wheeled counterparts.

Skateboards, roller skates, inline skates, compact kick scooters, and roller skis all have small-diameter solid wheels with a small contact patch. As opposed to the pneumatic tire of a bicycle, these wheels are generally made of solid urethane. These vehicles and some other nonmotorized vehicles do not have brakes, which makes emergency stops much more difficult and hazardous. Evasive maneuvers also can be more difficult with smaller solid wheels.

Nonmotorized vehicles with pneumatic tires and larger-diameter wheels are easier to manage on rough pavement and in variable conditions than small solid-wheeled vehicles. Kick scooters and other small-wheeled vehicles such as baby carriages, prams, and strollers may have either solid rubber tires or pneumatic tires, but the wheels generally have a much smaller diameter than bicycle wheels. These types of vehicles may or may not have brakes.

Running strollers are designed for higher-speed travel on uneven surfaces and, therefore, fare better than the typical carriage or stroller in challenging conditions. Electric mobility scooters also have small-diameter wheels, either solid rubber or pneumatic, and are subject to many of the same challenges as other small-wheeled vehicles. Motorized and nonmotorized wheel chairs typically have small front wheels and larger rear wheels.

Impact Speed

The speed of an object at the moment of impact is one of the primary variables that determines how much force is applied upon impact. Studies of automobile–pedestrian collisions consistently reveal that pedestrian injury and death rates increase at higher-speed impacts. In fact, there is a nonlinear increase in the risk of injury or death to the pedestrian at increased impact speeds. Nonmotorists are as vulnerable to automobile crashes as pedestrians, and, by extension, higher-speed traffic presents a greater threat to users of nonmotorized vehicles.

Variables That Improve Safety

There is safety in numbers; nonmotorists broadly and bicycle riders in particular are safer when there are more of them on the road. A number of studies point to increases in road safety as the number of bicycle riders increases.

When an individual is riding alone, he or she can follow best practices for active and passive safety. This means an individual can largely avoid or mitigate most hazards and vulnerabilities. Active safety includes maintaining control of the vehicle,

remaining visible, being predictable, following the rules of the road and traffic laws, using lane positioning and signaling to communicate movements and discourage others' mistakes, paying close attention to other road users and road hazards, learning to watch for and avoid other drivers' mistakes, and allowing buffers of space in all directions for slowing, stopping, and maneuvering.

Nonmotorists are advised to wear the appropriate safety equipment, including helmet, gloves, eye protection, and pads. Users of nonmotorized vehicles should familiarize themselves with the active and passive safety measures that are appropriate for the mode they are using. Motorists, meanwhile, can play an important role in improving safety for nonmotorists by looking for and expecting nonmotorists, yielding appropriately, passing safely, and being patient with some slowing of traffic.

Ocean Cruise Industry

Cruising is a luxury shipboard vacation in which passengers enjoy onboard amenities punctuated by visits to a series of exotic ports of call; it is about the journey, not the destination. Cruising is an alternative to resort vacations, but in total, cruise ships constitute less than 1 percent of worldwide hotel beds. However, cruising is growing in popularity, especially among North Americans, with an estimated 20.9 million passengers in 2013, a 3.3 percent increase over 2012. As a form of tourism, cruising has both positive and negative economic, sociocultural, and environmental impacts and poses some unique challenges in assuring the safety of passengers.

Cruise Lines and Ships

The cruise industry is highly concentrated, with the four largest cruise companies (Carnival, Royal Caribbean, Norwegian Cruise Line, and MSC Cruises) accounting for 96 percent of all passengers. The “big four” cruise companies are horizontally integrated with a variety of cruise lines, each of which is branded to serve a different market segment. Carnival is the largest operator, with nearly half of all passenger cruise lines that include Costa Cruises, Princess, Holland America, Cunard, and P&O.

The corporate concentration of the cruise companies reflects the capital-intensive character of the

industry. The first generation of cruise ships in the 1970s carried about 1,000 passengers, but the drive to accommodate more passengers and increase onboard revenues has emphasized economies of scale: larger ships and more elaborate onboard facilities. Most contemporary cruise ships carry between 2,000 and 4,000 passengers.

Most new cruise ships are built in Europe by shipyards experienced in the design and construction of cruise vessels, such as Fincantieri, STX Europe, and Meyer Werft. Cruise ship construction occurs in cycles, with several ships ordered, built, and entering the market within a short time. The biggest cruise ships afloat today, Royal Caribbean’s *Allure of the Seas* (2010) and *Oasis of the Seas* (2009), weigh 220,000 gross tons, cost about \$1.24 billion each, and took about four years to be delivered. They carry up to 6,300 passengers, with a crew of 2,700. Mega-liners such as these are floating resorts offering live entertainment, casinos, movie theaters, art galleries, shopping malls, skating rinks, rock climbing walls, golf simulators, multiple swimming pools, spas, health centers, exercise facilities, business and conference centers, and multiple dining venues. Countering the trend to larger ships, a tiny but growing cruising niche revolves around small vessels—yachts, rugged expedition ships, and classic schooners—where passenger counts can be as few as 10 and rarely exceed 200. These ships serve a more exclusive market segment focused on luxury,

personal service, and unique experiences such as visiting Antarctica, sailing a schooner around small Caribbean islands, or cruising European rivers.

Passengers and Profits

The United States is the world's largest cruise market, making up two-thirds of the global market. Cruise passengers are getting younger (average 46 years of age), with above-average (\$93,000) annual household income. Three-quarters of passengers are married and travel as couples; 16 percent bring children. Surveys of passengers suggest that food, family time, warm weather, relaxation, and romance are the most valued aspects of cruising. Moving away from traditions such as assigned dining times, seating, and dress codes, freestyle cruising has proven popular. Themed cruises that focus on music, dance, food, wine, or health, or distinctive market segments such as gay and lesbian customers, are another way cruise lines differentiate to attract passengers.

Ninety percent of cruises are booked through travel agents, and cruises constitute more than half of all travel agent vacation sales. What is novel with cruising is that the ship itself is the destination, which creates a captive market for onboard goods and services as well as shore-based activities, especially at facilities owned by the cruise line. The average passenger spends about \$1,700 for the cruise, including onboard and off-ship expenses. Onboard services account for between 20 and 30 percent of total cruise line revenues. Passengers spend an average \$100 per port of call, with three to five ports on a typical seven-day cruise.

Many cruise lines offer low-cost packages to boost passenger volumes, but premium options such as luxury suites and deluxe dining have greater profit margins. With a premium suite costing five times as much as a stateroom, these options effectively re-create the class system of 20th-century ocean liners.

Ports and Itineraries

The standard cruise itinerary is a loop beginning and ending at a hub port with the ship disembarking passengers in the morning and embarking new passengers the same afternoon. Hub ports must be accessible to a large customer market by a well-connected airport with significant airlift capacity and should themselves be tourist destinations (e.g.,

Miami, Barcelona). Larger cruise ships may use a fixed-base hub port and cruise the same region year-round, as *Allure of the Seas* does from Fort Lauderdale to the Caribbean.

About half of cruises last seven days; longer cruises have lower profit margins because passengers spend less as the cruise progresses. In developing itineraries, cruise lines focus on maximizing revenue, weighing passenger factors (seasonal demand, optimal cruise length, sailing time versus shore time, and "must see" destinations) against operational factors such as berthing capacity and nautical accessibility of ports and distance between ports (cruise ships can cover 200 nautical miles per night). Since cruise ships tend to have shallow drafts, the criteria for cruise ports differ from commercial ports; cruise ships are also able to anchor and use tendering services. Cruise ports tend to be near either city centers with cultural amenities or natural amenities such as beaches.

Climate is an important factor in itineraries. In the Northern Hemisphere, Baltic, Norwegian, Alaskan, and New England/Atlantic Canada cruises operate only in summer, while South American and Australian/New Zealand cruises operate only in winter (which is summer in the Southern Hemisphere). North America is the dominant embarkation region year-round; during summer, Europe accounts for 40 to 50 percent of embarkations. The Caribbean has long been the main cruise market and operates year-round with a summer low season. The Mediterranean also operates year-round with a winter low season. Together, these two regions comprise more than 70 percent of global cruising capacity. Repositioning itineraries are offered when ships move between seasonal markets and itineraries.

Impacts of Cruising

The U.S. cruise industry generates more than 450,000 jobs with \$15 billion in wages and billions more in the purchase of goods and services while also providing local revenues at the ports visited by its ships. The benefits of cruising for ports of call have been debated. When passengers are ashore for only a few hours on excursions planned by their cruise line, their experience of a destination may be a kind of constructed fantasy that is an extension of their ship, leaving them with little real insight into the destination and providing limited local economic benefit.

Three cruise ships, including Princess Cruises' Star Princess (950 feet), Holland America's Zuiderdam (955 feet), and Westerdam (936 feet) are berthed in the Port of San Diego, October 4, 2012. At left is the decommissioned aircraft carrier U.S.S. Midway, which was the largest ship in the world (at 972 feet) until 1955; it has served as a naval aviation museum since 2004.

According to the International Transport Workers Federation, cruise ship workers are underpaid, have poor working conditions, limited leisure time, unsatisfactory accommodation, and few rights. The ethnic diversity among crew combined with a top-down marine industry management style can make it difficult for crew to improve their situation.

Cruise ships make up less than 1 percent of the global merchant fleet, yet it has been estimated that they are responsible for 25 percent of all waste generated by merchant vessels. Cruising cannot be considered a sustainable form of tourism because cruise ships consume significant resources and ships and passengers have environmental impacts on their destinations, especially in "ecologically vulnerable" regions (for example, Alaska or the Caribbean). Cruise lines have, however, adopted more environmentally sensitive practices and onboard waste disposal, recycling, and sewage treatment technologies to reduce their environmental impact. With these measures, the cruise industry claims to be approaching "zero discharge."

Passenger and vessel safety has received more attention recently, especially after the *Costa*

Concordia tragedy left 32 dead in January 2012. Of all travel industries, cruising is the least governed by national regulations. Companies register their vessels where the costs are lowest and the oversight and requirements are fewest; most of today's cruise ships are registered in the Bahamas, Bermuda, or Panama. Once a ship travels beyond 200 nautical miles from shore, it is regulated by the International Maritime Organization (IMO) and its flag country. The IMO lacks the authority to enforce its own guidelines and is unable to impose fines or sanctions on cruise lines that do not meet Safety of Life at Sea recommendations, and the flag states rarely enforce them. The U.S. Coast Guard conducts annual Certificate of Compliance inspections as well as announced and unannounced inspections of every cruise ship embarking passengers in U.S. ports to ensure the vessel meets all international conventions and domestic requirements for safety, security, and environmental protection.

Ocean Passenger Travel

Ocean passenger travel is performed principally by passenger ships, a category of merchant ship, although a small amount of passenger travel is done on cargo ships, which sometimes offer a small number of passenger accommodations. Before air travel became more widespread, these ships, most of which carried fewer than 20 passengers, were a common method of travel. Most ships that carry passengers on the ocean today are ocean liners, cruise ships, or ferries.

Ferries typically take passengers (and sometimes vehicles) only on brief trips, especially of commuting or "water taxi" distance. When ocean travel is involved, ferries will usually go only so far as a nearby island, or from one part of the shore to another. That said, ferry service is also offered from southeast Alaska to Bellingham, Washington, which takes at least a day.

In recent years, the ocean passenger travel industry, which in the United States serves about 10 million people a year, has shifted in favor of larger ships, lower fares, and departures from more ports (so that fewer passengers need to arrange travel to the port of departure). Nearly half of passenger ships depart from three Florida ports: Miami, Port Canaveral, and Fort Lauderdale. This is in part due to the climate, but also because Florida's chamber of commerce and legislature have long incentivized travel and tourism businesses to operate in their state.

In general, smaller ships have been relocated to overseas operations in favor of larger vessels in

the United States. For instance, Royal Caribbean's *Oasis of the Seas*, launched in 2009, has a capacity of 6,000 passengers, the size of a small suburb. Larger vessels have made the work of passenger security screening at passenger terminals more difficult, while also taxing the infrastructure of those facilities. The Maritime Transportation Security Act of 2002, passed in response to the terrorist attacks of September 11, 2001, requires all passengers and luggage to be screened by metal detectors and X-ray scanners when those passengers are embarking or disembarking.

Since 2012, cruise lines have been required by an industry-adopted safety policy to conduct passenger safety drills before leaving port. This was adopted in response to the January 2012 *Costa Concordia* disaster in which the cruise ship crashed into rocks near the shore of the island of Giglio off the western coast of Italy, resulting in dozens of deaths and missing persons. About one-fifth of the ship's passengers had not attended the ship's safety drill, which had been conducted before they had boarded.

Passenger Travel Becomes Specialized

Passenger freighter travel does still exist and is preferred by some travelers because the ships are less crowded and lack the same culture and atmosphere as cruise ships. It is also more common in some parts of the world than others. Freighter travel is the principal mode of passenger ocean travel on the Caspian and Black Seas, for instance, and is common throughout much of the third world, where maritime trade is common.

Today, if there is no ship's doctor aboard, international regulations limit the passenger count to 12. There are significant drawbacks to freighter travel; passenger service is often an afterthought, and schedules can change at a moment's notice because of conditions that are related to the transport of the ship's freight. Food is not always provided, and arrival times at the final destination are often unpredictable. Usually passengers are given a small cabin and eat alongside the crew in the mess hall. They may also be given access to other crew common areas. Not all passenger cabins have their own bathroom.

Standards of what passengers can expect vary according to the country in which the freighter is registered. That said, freighter travel also offers

Guests enjoy the swimming pool on the German-built AIDAvita cruise ship, part of the British AIDA Cruises company fleet. The AIDAvita can carry up to 1,266 passengers and 426 crew, far fewer than many of the newest ships operating in the United States. The U.S. ocean passenger travel industry caters to about 10 million people a year, with some of the very largest ships, such as Royal Caribbean's Oasis of the Seas and its sister ship, Allure of the Seas, carrying upward of 6,000 passengers at a time.

unique trips that the cruise industry may not, including the aforementioned Caspian Sea, or a trip from the Great Lakes to western Europe. Further, if food or drink is made available for sale, it is considerably cheaper than on cruise ships, because it is an insignificant source of revenue for the freighter. Freighter travel is also often available from smaller ports than cruise ships, which tend to leave from major hubs. However, the security measures adopted since September 11, 2001, have reduced the number of smaller freighters accepting passengers to or from the United States.

Freight, however, can travel on passenger ships, which, with the exception of cruise ships, usually include a freight hold. Ocean liners carried equipment for freight handling, but today this is true only of the older ships in the fleet, and the capability often goes unused.

Crews of merchant ships, including all passenger ships and freighters, are members of the merchant marine. The U.S. merchant marine consists of the crews of the merchant ships owned by U.S. citizens and registered in the United States. Other crews, including on ships owned by American businesses but registered overseas, may be members of the merchant marine of other countries.

During wartime, the merchant marine is considered an auxiliary service to the navy and may be pressed into service to transport troops or supplies, but it has no combat role. Merchant seamen are not military personnel, although they may use ranks similar to those of the military, including captain, mate, and other titles.

Origin–Destination Models

An origin–destination (OD) model is fundamental to understanding travelers' flow pattern for any specific transportation or region. The model has been widely used to understand characteristics of travel demand. The results can be used for transportation demand management, planning, and policy. This introduction to OD models covers its definition, data, methods, and applications.

Definition

The OD model can be defined as a way to represent the flow of travelers between their origin and destination for any specific transportation mode or region. The major difficulty of OD modeling is obtaining accurate estimation to represent these flows in origin-to-destination tables. Thus, the OD model is the basis of trip distribution, destination choice, or zonal interchange analysis, which is the second step in the four-step transportation forecasting model. Information on trip distribution is presented in a two-dimensional square OD matrix denoting volume of demand flows. Depending on the specific research

purpose, trip distribution of an OD table can be represented by numbers of trips, numbers of passengers or freight volumes, or numbers of traffic counts.

Data

To estimate OD demand is a challenging and costly task because it requires a large amount of OD-specific data. Data can be obtained in different ways, ranging from a large-sample OD survey and traffic monitoring system to physical road counters. The monitoring system, sometimes also called an automatic vehicle identification system, collects OD information of vehicles through two or more cameras placed separately at certain distances, or by local street sensors or monitoring cell phone signal (CPS) movement and distribution.

The OD information of each vehicle can be identified through vehicle plate recognition. In addition, vehicle information such as travel time and distance can be automatically calculated based on the information recorded by cameras or cell phones. In recent decades, because of the development of Intelligent Transportation System (ITS), traffic data can be obtained in a much more timely and efficient manner. Traffic counts can be observed at very short time intervals by traffic monitoring systems. This information can then be used for time-dependent OD modeling.

Despite the use of both surveys and the advanced traffic monitoring system, which provide solutions for OD data collection, the financial constraints of using a sampling survey and traffic monitoring system still prohibit collecting data for the whole population. In order to complete the OD matrix of the population, some mathematic algorithms are developed to estimate missing data.

Methods

Classic transportation forecast modeling is conducted in four steps: trip generation, trip distribution, mode choice, and traffic assignment. The OD model is used at the second step to generate information on trip distribution in the form of trip tables.

The OD table is the central goal of OD modeling because it displays the distributions of trips going from origins to destinations. The conceptual framework of an OD table is illustrated in Table 1. The table is an $n \times n$ matrix. The row of the table represents place of origin, while the column represents place of destination. Each cell in the table indicates

the numbers of trips or passengers from origin i to destination j . The task of OD modeling is to fill in the cells for the tables headed 1 to n .

Theoretically, OD data can be obtained through an OD travel survey or collections from traffic monitoring systems. In reality, it is normally impossible to fill the whole OD table with the collected data as travel surveys, while the traffic monitoring system is only able to provide sample data instead of the whole data population. Therefore, to complete the whole OD matrix, it becomes necessary to fill all the blank cells using estimation approaches. Further forecasts are built on the estimation of potential flows from land uses that do not yet exist but need to be planned for in terms of infrastructure support for future need.

The basic rationale for OD estimation is to find the relationship between the missing data and the sample data based on traffic counts. Assuming the traffic-counts data is collected from a roadside survey, the expected OD link flow D_n is the missing data that needs to be estimated. It can be expressed in equation (1):

$$D_n = k \in K p_{kn} T_k \quad n \in N \quad (1)$$

where p_{kn} denotes the proportion of OD trip pair $k \in K$ through the link n , and T_k denotes the total number of OD trip pair $k \in K$, which is given in the sample data.

In order to achieve a unique solution for the equation, additional information between the estimates and sampled data is needed and should be specified. There are plenty of techniques to build this linkage, such as the Fratar (growth) approach, intervening opportunities, neural network, gravity/spatial interaction approach, and entropy estimation. Each approach provides a unique mathematic algorithm for data estimation.

In this introduction, the four most widely used OD forecasting methods are presented: the gravity/spatial interaction approach, the entropy approach, the equilibrium approach, and the dynamic OD estimation.

Gravity/Spatial Interaction Approach

The gravity/spatial interaction approach illustrates the macroscopic relationships between places (such as home and working place). The method is often used to model interactions between the trip matrix and related parameters, such as distance, time, cost, and other activities associated with each location. The basic gravity approach for estimating an OD matrix based on trip distribution data can be expressed in equation (2):

$$D_{ij} = i_j O_i D_j A_i B_j f_{ij} p_{ij} \quad (2)$$

where D_{ij} represents the flows in particular link from i to j . O_i and D_j are the trips produced from zone i and attracted by zone j respectively, and f_{ij} denotes a deterrence function; p_{ij} is the proportion of trips traveling from zone i to zone j . A_i and B_j represent the balancing factors.

The estimation can be conducted using nonlinear least-square regression, weighted nonlinear least-square regression, or maximum likelihood estimation. Applications of gravity approach to OD estimation are extensive. For example, Pierre Robillard from University of Montreal, Canada, and Per Högborg from University of Göteborg, Sweden, have adopted the gravity approach to achieve OD matrix estimation based on data of traffic counts.

However, the gravity approach has a critical disadvantage. The estimation is not inclusively accurate when “external” or “through” trips are included in the analysis. Although the origins or destinations (or both) of these trips are outside the area of interest, they are usually unnecessarily combined or included in analysis. As a result, travel demand for each OD pair may be overestimated if these external trips are not separated out.

Entropy Approach

Alan Wilson from University College London, developed another algorithm for transportation OD matrix estimation. The algorithm is known as the “entropy approach.” The concept of entropy originates in thermodynamics, which is mathematically

Table 1 Origin-destination table

Origin	Destination			
	1	2	3	n
1				
2				
3				
n				

defined to account for the flow of energy through an energy process.

In its later development in statistics, entropy is defined as “a measure of the loss of information in a transmitted message.” The entropy approach includes two categories of methods: the entropy information minimization approach and the entropy maximization approach.

The entropy maximizing procedure analyzes the available information to obtain a unique probability distribution of OD trips. Assume a set of origin zones, labeled i , and a set of destination zones, labeled j , and let D_{ij} be the matrix of flows from i to j . The traditional gravity model can be written as equation (2). The problem with this model is that the predicted D_{ij} does not satisfy

$$jD_{ij} = O_i \quad (3)$$

where j represents the sum over all destination zones, and

$$iD_{ij} = D_i \quad (4)$$

The number of possible combinations for trip distribution can be described in equation (5):

$$W = D! / i! j! \quad (5)$$

where D represents the total numbers of trips and ij is the product over all i and j , and $!$ represents “factorial.” The number of combinations associated with a particular OD matrix D_{ij} can be taken as the probability that the given D_{ij} occurs. In addition, the constraints of trip distribution can be written as

$$ijD_{ij}f_{ij} = F \quad (6)$$

where F is assumed to be the total transportation deterrence constraints (measured either by time cost or expenditure) and the sum is over all i and j . The most probable state can be found by maximizing W in equation (5), subject to equations (3), (4), and (6). According to Wilson’s approximation approach, W can be transformed to the form

$$W = -ijD_{ij}\log(D_{ij}) \quad (7)$$

which can be recognized as a form of entropy, yielding the notion of the “entropy maximizing models.”

In the circumstance where additional information besides traffic counts is available, the information entropy minimizing approach can be applied for the estimation. Two other scholars, Henk J. Van Zuylen and Luis G. Willumsen, have made great contributions to develop this method.

However, as pointed out by Sharmintha Bera and K. V. Krishna Rao from the Indian Institute of Technology, Bombay, both the entropy information minimization approach and the entropy maximization approach have the disadvantage of not considering the uncertainties in traffic counts and prior matrix, which they believe can be erroneous and can influence the estimation output.

Equilibrium Approach

Both the gravity approach and the entropy approach are early techniques of OD modeling that relied on the assumption that travel time is invariant among all transportation networks. However, in the real world, travel time varies significantly depending on the severity of road congestion, especially in urban areas and networks operating near capacity. To remedy this estimation drawback, the “equilibrium” or “combined” solutions were developed, which consider the influence of congestion in the form of feedback effects. Sang Nguyen, Mark Turnquist, and Yehuda J. Gur are the contributors to the algorithms of OD estimation under equilibrium assignment.

The equilibrium assignment approach assumes the knowledge of the travel costs between each OD pair. This relationship can be represented, as Nguyen and Willumsen have done, by:

$$\text{Min } FV_{lm}, T_{ij} = lm0V_{lm}clmxdx - ijcijT_{ij} \quad (8)$$

Subject to

$$\begin{aligned} T_{ij} - rT_{ijr} &= 0 \quad \text{for all } i, j \\ T_{ijr} &\geq 0 \quad \text{for all } i, j, r \\ T_{ij} &\geq 0 \quad \text{for all } i, j \\ V_{lm} &= ijT_{ijr}\delta_{ijrlm} \quad \text{for all links} \end{aligned}$$

where clm is the cost-flow relationship for link lm , and cij denotes the observed cost of traveling between i and j . T_{ijr} is the number of trips between i and j via route r . δ_{ijrlm} equals 1 if route r between i and j uses link lm ; otherwise, it equals 0.

As noted by Nguyen, this equation has the same structure as the traffic assignment model with elastic

demand. He suggested an algorithm for its solution that starts with an OD matrix, and provided adjustments to create a convergence. His problem has a unique solution in link volumes but not in the OD matrix. As a result, this solution is consistent with equilibrium assignments and observed flows.

Dynamic OD Estimation

The aforementioned OD demand estimation considers the trip distribution in a static scenario. The problem with such a static model is that it does not include the time character of traffic flow dynamics. It assumes that the observed flows are in a steady-state situation. Recently, there has been an increasing interest in developing dynamic OD estimation methods for transportation forecasting and planning.

The dynamic OD estimation also refers to a time-dependent OD demand estimation. It differs significantly from the static OD demand estimation in that the target demand table is estimated based on historical OD demand data and other archived traffic information, which is able to capture network system dynamics. There are several approaches for dynamic OD estimations, such as the state-space modeling, Kalman filtering approach, and two-stage demand estimation. Kalidas Ashok and Moshe Ben-Akiva from Massachusetts Institute of Technology and Xuesong Zhou and Hani S. Mahmassani, from University of Maryland at College Park have made substantial contributions to expanding the applications of dynamic OD estimation.

Applications

One of the major applications of OD modeling is to understand travelers' true origins and destinations for any specific mode, city, or region. It can be used to analyze travel demand and traffic volume distribution. Take aviation, for example. On a flight from Washington Dulles International Airport to Chicago O'Hare International Airport there will be numerous passengers with many different origins and destinations. One passenger may only be traveling from Washington, D.C., to Chicago; another could be connecting in Chicago to fly to St. Paul, Minnesota; and a third may have started his journey in Charlotte, North Carolina, and connected in Washington to travel to Chicago and onward to Shanghai, China. In this simple example, the one single flight from Washington to Chicago serves the demand for at least three different ODs:

Washington, D.C., to Chicago; Washington, D.C., to St. Paul; and Charlotte to Shanghai.

Measuring only the volume of passengers traveling from Washington, D.C., to Chicago would overstate the Washington-to-Chicago OD but would not reflect the demand on the other ODs flowing over the route. An OD model enables us to estimate the true travel volume by city pair based on the passengers' entire journey, and it allows airlines, airports, and tourism organizations to better understand, plan for, and serve their markets. Obviously, similar applications can be found in other modes, such as highway traffic studies and transit demand studies.

In most applications, the OD model is used with a combination of other methods, such as regression analysis, to help identify casual relationships between external variables and the OD distribution patterns. For example, William Crown at Brandeis University has conducted a study using an OD model to investigate the direction of the relationship between inter-regional migration and regional employment growth.

In his analysis, an OD model was applied to the inter-regional migration flows for the population under age 60 during 1975 to 1980 in the United States. The model found that people tend to move either to a nearby state in the same region or a popular destination area, such as the south Atlantic or Pacific region. The relationships between inter-regional migration and regional employment growth were examined in a simultaneous equations model using data from the OD model. The results show that manufacturing growth and migration are jointly determined, and that manufacturing growth has a stronger effect on migration than vice versa.

Another application of the OD model is to prepare OD distribution data for mode choice analysis. The information on trip distribution can be further used to understand the characteristics of travel demand. To achieve this objective, travel demand between each OD pair is estimated first in an OD model, which is then treated as a dependent variable. Explanatory variables usually include level-of-service variables (travel cost, on-vehicle travel time, and out-of-vehicle travel time) of specific modes and their competing modes, and social and demographic variables (such as population, personal income, and race) of both origin and destination, as well as the distance between an origin and a destination. Mode choice analysis allows decision

makers to determine which mode of transport will be used and which modal share results.

The OD model can also be applied to understand inter-regional flows of trade, migration, or transportation activities in a spatial context, if combined with spatial econometric techniques. Unlike traditional modeling analysis, which relies on the assumption of independence among OD flows, the integration of spatial econometric estimation with the OD model allows researchers to measure the spillover effects of inter-regional flows. This is because of the assumption of spatial dependence among the observations of OD flows. This is more realistic because the distribution of transportation OD flows is often influenced by geographic characteristics.

For example, in their Canadian journey-to-work flow study, Daniel A. Griffith and Kenneth G. Jones found that traffic flows from an origin are converged or diminished in accordance with the propensity of emissiveness of its neighboring origin locations, while the flows to the destination are influenced by the characteristics of its neighboring destination locations.

Under spatial econometric OD modeling, conventional gravity-like equations can be added to a spatial weighted matrix of OD flows or spatial weighted matrices of explanatory variables so that any spatial dependence can be controlled for. In general, spatial econometric OD modeling is valuable when the OD flow data has an issue of spatial dependence. The method provides a spatial perspective for examining OD flow patterns.

Paratransit in Developing Countries

“Paratransit” is used as a general term for a “demand-response” travel mode, which is operated under more flexible operation and service arrangements than traditional fixed-route public transport systems. In developed countries, it typically represents a shared vehicle system for prearranged trips for riders who are eligible for the particular services (for example, people with special needs).

In developing countries, though, it mostly represents a local public transport system, which is characterized by flexible fares, unscheduled operations, and semifixed routes. Customers appreciate paratransit systems because of the degree of flexibility they provide, relatively lower operation and administration costs for the operators and government, relatively lower fares for the users, and higher labor intensity. On the other hand, because the system is mostly developed by the community or by private initiative, it is harder for it to be regulated by the government, leading to difficulties in not only standardizing the level of service but also other practical aspects, such as fares, safety, and the size and vehicle-type of fleets.

Paratransit is an alternative mode of public transportation that is provided by private or public operators for a certain group of users or to the general

public. This mode of public transport is adaptable in its routing and scheduling to individual users’ and/or operators’ desires in varying degrees. While the implementation and the use of this mode differs in developed and developing countries, it ultimately fills gaps not being served by private cars, buses, and other fixed-route systems.

Typically, vans or minibuses are used to provide paratransit service. In some countries, it is also common to use taxis, jitneys, modified station wagons, three-wheelers, and motorcycles.

In developed countries, paratransit is often used for demand-responsive systems, such as shared-ride taxis, dial-a-ride cars, and subscription or community buses. When it was introduced in the 1970s, paratransit was thought to be an ideal public transport service provision for users in areas of low-density land use and low demand (that is, areas not served cost-effectively by conventional public transport systems). Recently, it has been commonly used as a public transport system for people with special needs, such as travelers with various disabilities.

This service includes the U.S. Americans with Disabilities Act (ADA) paratransit system, a service required by the U.S. federal government after the 1990 passage of the act (only people who have been certified by the Regional Transportation Authority as a person with a disability are eligible to ride this service), and Call-n-Ride, a service that

A motorbike delivers milk and goods outside the city of New Delhi, India. Over half of all public transport needs are fulfilled by paratransit services in large cities in developing countries.

is similar to dial-a-ride, except that everyone is eligible and passengers can reserve a trip only one hour in advance.

In developing countries, paratransit is often used as the backbone of the public transport system. The lower standard of living, higher population density, and availability of a cheap labor force have together provided a bewildering array of transport modes bridging the gap between a fixed public transport system and private automobiles. More than half of the public transport demands in major cities in developing countries are served by paratransit, comprised of formally and informally operated minibuses, vans, taxis, station wagons, three-wheelers, motorcycles, and, in some cases, informally operated buses.

Rapid increases in urban population and per capita income, along with inadequate existing transport infrastructures and the lack of governments' fiscal and institutional capacities, have stimulated paratransit usage as an inexpensive and convenient public transport mode. However, some operators have neither official endorsement nor appropriate licenses, permits, or registration papers from public authorities to allow them to provide collective-ride services to the general public. Most drivers are low-skilled younger men who

migrate to cities from the countryside. The overabundance of idle labor in cities such as Jakarta, Indonesia; Nairobi, Kenya; and São Paulo, Brazil, makes informal transport an attractive employment opportunity.

Operation and Service Characteristics

The delivery of paratransit services may vary considerably as far as the degree of flexibility they provide their customers. Basic paratransit offers a service from a user-specified origin to a user-specified destination at a user-specified time. The basic service is modified to offer service only to provider-specified destinations or, in some cases, one destination, such as a site for social or medical service provision. In practice, the simplest service may consist of a taxi or small bus that runs along a more or less defined route with regular stops or allows passengers to alight on request.

At the other end of the spectrum—fully demand-responsive transport—paratransit systems offer the most flexible, on-demand, call-up door-to-door service from any origin to any destination in a given service area. In developing countries, paratransit modes range from simple nonmotorized human- (mainly hand-drawn or pedal-driven) or animal-powered vehicles to motorized minibuses. These paratransit modes are designed to provide flexible and frequent services to small communities and through narrow streets (where no other services operate) at a relatively low fare.

In terms of functional characteristics and service patterns, paratransit modes can be classified into three separate groups. The first is the “individual” type of paratransit, which provides a door-to-door service. For the second and third groups, the “shared” and “collective” types, the routes are generally fixed, but vehicles often and marginally deviate from the route based on passenger demand. The collective-type paratransit service sometimes cuts routes to pick up passengers going in the opposite direction.

Paratransit services can be operated by public transport agencies, community groups, or not-for-profit corporations, as well as by for-profit private companies or operators. Private individuals and cooperatives own the vehicles used for paratransit. Survey results in developing countries indicate that most drivers rent their vehicles from small-scale enterprises, with very few drivers owning their

vehicles. For example, only 9 percent of the jeepney (jeep-jitney) drivers in Manila; 18 percent and 13 percent of becak (bicycle-trishaw) drivers in Bandung and Jakarta, respectively; and 1 percent of samlor (pedicab) drivers in Bangkok are estimated to own their vehicles.

Mostly, the fares of individual-type paratransit modes are decided through negotiation between passengers and drivers. Some countries, such as India and Nepal, have metered auto rickshaws. But, in case of shared or collective types of paratransit, fixed fares are typically received from passengers, although, in some countries, the system can be more flexible, depending on the operator/driver.

Paratransit service providers who operate under a laissez-faire environment have to survive on low profit margins and to actively, and sometimes dangerously, compete for customers. This gets expressed as stopping almost anywhere to board passengers, driving overloaded vehicles, and using unsafe driving habits—what economists call “collectively damaging behavior” and is termed in Latin America, *la guerra del centavo* (the war for the cent). In this same vein, operators often “cream-skim,” offering frequent services at peak times and in peak directions, while leaving off-peak riders waiting until vehicles fill—sometimes for an hour or more.

To protect their interest, in many countries, these small transport providers join forces to form cooperatives. Cooperatives might be related to specific areas of the city or even a specific route, thereby called “route associations.” Cooperatives and route associations serve to organize the members in ways that increase the total ridership and profit of the routes, while also ensuring that all operators gain fairly equal shares of total revenues. In many countries, these cooperatives also act as organizational bodies that negotiate with the government over regulations and fares.

Advantages and Disadvantages

Each transport mode has its positive and negative consequences. Although the characteristics of paratransit modes differ based on their functions in different cities, commonalities include the fact that these modes are the usual means of movement among low-income individuals, cheap fares, low energy requirements, and higher labor intensity. Therefore, in some cities in developing countries,

the paratransit sector also generates a considerable number of employment opportunities.

For example, in India and Bangladesh, the share of employment generated by cycle rickshaw services is 12 percent and 12.9 percent, respectively. Further, most of these paratransit services are initiated and provided by the community. This is a significant help for the municipal governments in poorer cities, where budgets are stretched thin and technical capacities for planning, administration and regulation are insufficient.

Even in more modern settings, paratransit can be an important gap filler. Hong Kong's Public Light Bus entered the market to feed key train stations and housing and was later formally regulated by city officials. Mexico City's *peseros* (minibuses) were initially allowed because they could substitute for, without a need for subsidies, the failing public bus system.

The paratransit system has remarkably deep territorial coverage and integrates both planned and unplanned low-income neighborhoods into city economic and social systems. Recent studies also suggest that some types of paratransit services are instruments of social encounter and cohesion.

Taking advantage of compact vehicle size and unrestrained operation, paratransit can admirably respond to fluctuating markets, fill voids at relatively low fare in areas left by public transports, and substitute for much-needed public transport services without subsidies. They also respond quickly to changing markets, are more in tune with their passengers' demands, and have relatively low costs. By organizing into route associations and cooperatives, some operators can lower per seat costs to the point of being competitive with larger companies, research shows.

On the other hand, unlike a conventional bus service, the paratransit modes have no obligation to provide a service on those routes where demand is low. The operators provide services only where and when it is profitable for them. Often, to achieve more profitability, the shared and collective types of paratransit do not leave the terminal until the vehicles are full, leading to longer passenger waiting time and lower journey satisfaction.

Because the paratransit system mostly developed by community or market initiative, it is also harder to regulate by the government, leading to difficulties in not only standardizing the level of service

but also other practical aspects, such as fares, and the size and vehicle-type of fleets. In Mexico City in the early 1990s, for example, the rapid growth of the local paratransit services, which had gone from just 10 percent of the 30 million motorized trips daily in 1980 to 50 percent 10 years later, provided the minibus owners with unprecedented political power. This puts the regulators at a disadvantage in developing more structured and planned public transport services.

On-the-ground relationships between paratransit and the existing planned services are also far from stable, with that relationship vulnerable to descending into destructive competition for passengers. Within the general public transport system, the planned public transport services usually occupy higher-demand corridors and provide a relatively higher quality of service, while paratransit services are frequently (but not always) located on less desirable corridors and/or areas with physical accessibility constraints. This creates tension between the two systems and any improvements/upgrades of planned services tend to create social unrest among paratransit users.

Other negative effects include paratransit's contribution to the overall reduction in traffic speed and the decrease in road capacity, which can cause appreciable congestion. In many developing countries, paratransit's indiscriminate stopping and starting may hamper the normal flow of traffic. For example, in Jakarta, in terms of road space utilization per passenger, it is estimated that paratransit was 10 to 13 times more inefficient than a conventional bus.

There is also some indication that the use of paratransit significantly contributes to the road traffic accident rate. This remains a hard-to-regulate practice, and operators sometimes have the opportunity to drive up fares until it becomes an almost inaccessible mode of transport for the urban poor, as was the case with the *matatu* in Nairobi.

Conclusion

While modern mass rapid transport systems, such as the tram and urban rail, may relieve transport and traffic congestion problems, these systems require a huge capital investment and take a very long time to build—something that is almost impossible for most developing countries or low-density areas in developed countries to have. In

such circumstances, paratransit modes will still be able to serve the community in a much cheaper, quicker, and more responsive way than the fixed public transport system.

Park-and-Ride/ Kiss-and-Ride Lots

Park-and-ride lots are provided for the purpose of facilitating patronage of fixed-line transit by aggregating ridership from a low-occupancy feeder mode (that is, private vehicles). Park-and-ride has been very successful in increasing the patronage of public transport systems within sprawled North American and Australian cities and the transit mode share of residents in suburban and ex-urban locations generally.

Park-and-ride lots are most typically associated with metro or heavy rail rather than bus rapid transit (BRT) or light rail transit (LRT). This is because the catchment of metro and heavy rail stations is larger, these systems have higher capital and operating costs, and they are designed to facilitate longer (regional or subregional) trips than BRT or LRT.

Park-and-Ride Yield and Function

The yield of park-and-ride bays and their design and their orientation to the transit station often depend on two key factors:

1. The broader form and function of the station. This includes whether it serves as an interchange between feeder bus services and fixed-line transit, or is embedded within a transit-oriented development (TOD) precinct, which generates a significant proportion of walk- and cycle-on patronage.
2. The distance of the station from the central business district (CBD).

There is a clear relationship between the two variables, with stations farther from the CBD often having relatively fewer TOD characteristics. There is also less opportunity for sufficient patronage to be generated locally to warrant investment in and operation of an outlying station along a transit alignment without provision of park-and-ride.

Park-and-ride lots are particularly popular in contexts where there is a requirement for patronage targets to be hit early following the opening of new transit stations and a low perceived (and sometimes actual) market appetite for TOD, which could be an alternative source of patronage. Logically, this most

often applies in suburban and greenfields train station locations.

Park-and-Ride User Groups

The typical park-and-ride user is a commuter. This reflects the radial characteristics of many fixed-route transit systems. While there may be some churn of bays over the course of a weekday, overall occupancy may remain quite static. Moreover, depending on the supply of park-and-ride relative to demand, commuters may need to arrive in advance of their preferred travel time on transit to secure a bay. Over time, park-and-ride may fill earlier and earlier because of this adjustment to travel times.

For these reasons, park-and-ride tends to contribute to peak-travel-demand management issues, meaning it encourages and concentrates transit trips inbound to the CBD during the morning peak and outbound in the evening peak. Peak travel demand is a growing issue in many cities, because it requires high capital and operational expenditure to supply the capacity necessary to meet short-run tidal flows on the transit system.

The use of park-and-ride by noncommuters will be higher in cities where there are more circumferential transit lines and decentralization of jobs. However, these cities are also likely to have fewer park-and-ride provisions overall, because of the greater potential for rail patronage to be generated by feeder modes other than private vehicles. Such cities, including many in western Europe, Singapore, and Hong Kong, are also less likely to experience one-way peak travel demand problems.

Park-and-Ride Location

From a planning perspective, it is desirable to locate park-and-ride within a reasonable walking distance of the station, but without compromising station access for other modes of feeder transport. A walking threshold of around 450 yards (411 meters), or about a five-minute walk, is often accepted; however, this has to be considered in the context of peoples' overall journeys. For example, there may be a number of legs to a commuters' typical journey to work (for example, drive-transit-transit-walk), and the imposition of a five-minute walk from their parking space to a rail service could be sufficient to encourage them to drive to work instead. This also depends on the availability and cost of parking at the end destination and levels of congestion on the road network.

A sign marks the park-and-ride lot at the Chicago Transit Authority's Garfield station in Chicago, Illinois. Planners aim to have park-and-ride facilities within a five-minute walk (or about 450 yards or 411 meters) of transit stations.

Determining the location for park-and-ride involves a series of trade-offs, depending on the extent to which a planning authority wishes to favor different feeder modes. Even so, it is critical for the authority to remember that even park-and-ride users become pedestrians when they exit their vehicles and walk to the transit station platform. This necessitates provision of appropriate pedestrian infrastructure within the park-and-ride lot.

Vehicle access to park-and-ride lots is also an important consideration, and this depends on the geography of the local road system. Furthermore, land tenure and use may limit where the park-and-ride can be constructed. In some instances, a series of smaller park-and-ride lots are provided in lieu of a larger facility to try to address this range of station-specific issues. However, this is less spatially

efficient because access points, aisles, and internal pedestrian infrastructure are still required within each facility.

Kiss-and-Ride

Kiss-and-ride is distinct from park-and-ride because the bays provided must be within closer proximity to the stations to permit drive-up drop-off and pickup of passengers.

Kiss-and-ride bays experience high turnover—notably in peak hours—because they are specifically designed to discourage longer-term parking. Thus, they are a more spatially efficient mechanism to increase transit patronage; however, they require a trip by someone other than the transit patron who is able to make the trips to and back from the station. For this reason, kiss-and-ride bays are usually provided in conjunction with park-and-ride facilities. Because the idea of kiss-and-ride is quick depositing and retrieving of passengers from cars—which results in the high churn of traffic and spatial efficiency—kiss-and-ride is generally placed in greater proximity to the station than park-and-ride.

Parking Management

Given the well-established relationship between park-and-ride and kiss-and-ride and their ability to increase patronage of public transport, transit authorities may be loath to charge users of the facilities. While price elasticities may be relatively low, the introduction of or increase in costs of parking may induce some users to switch completely to car-driver trips.

Parking is not free to provide, though, and there is increasing understanding from the public that at least some of the cost of supply and operation is necessary to be recouped to ensure the longevity of the service. In Perth, Australia, in some station precincts, the park-and-ride fee is priced to be roughly equivalent to a typical feeder bus fare, which also helps avoid any alienation of either feeder bus or park-and-ride users. Often the parking lot for which a charge is levied provides additional amenities, such as security fencing, closed-circuit TV, and lighting.

Control of access to park-and-ride poses further challenges. While the intent of supplying park-and-ride is to benefit transit users, park-and-ride facilities can be attractive to non-transit users, too, particularly if public parking supply in the vicinity is

limited or costs more. For example, public parking that serves retail or commercial land uses may cost several times more to use than an adjacent park-and-ride lot. The opposite is also true in the case where parking associated with retail or commercial land use is provided free to customers. This may tempt some park-and-ride patrons who are required to pay for parking to take advantage of the free parking.

One method to control the use of park-and-ride is to link payment to the use of transit. This requires some sort of smart system whereby the transit authority can validate use of park-and-ride by confirming that the user is a bona fide transit patron. The introduction of smartcards in some cities, such as the San Francisco, California, metropolitan area's Clipper Card, enables the integration of park-and-ride and transit-fare payment by providing an electronic mechanism for this service to be performed.

Long-Term Opportunities and Constraints

Park-and-ride lots may sometimes be intended to function as land banks. Because they are often situated on public land and maintained and operated by a government agency, planners might have a longer-term plan to replace at-grade lots with decked structures when the market is able to supply sufficient local activity intensity to generate patronage through other feeder modes. However, there are often difficulties making such changes to park-and-ride once it is constructed, because of the following:

- Existing at-grade park-and-ride can create poor amenity within close proximity to stations, which can be a disincentive for investment in TOD opportunities by developers who are leading the market.
- The cost of supplying park-and-ride in decked structures is significantly higher than at-grade facilities, which often becomes a cost imposed on the private-sector developers the government requires to fund the conversion.
- Even reduced park-and-ride supply can generate significant general-vehicle trips within close proximity to stations during peak periods, which can affect feeder bus operations and pedestrian and cyclist amenities.
- Park-and-ride tends to generate a large station catchment; patrons who become

accustomed to using the park-and-ride will tend to oppose any reduction in the supply of facilities they rely on to fulfill their travel needs. This may be their only means of gaining access to rail transit.

Selling of air rights over park-and-ride lots is gaining popularity in North American and Australian cities as a means to help fund the conversion of at-grade park-and-ride lots to decked structures. The right to development is usually highly valued, given the land premium that tends to be associated with proximity to stations.

This system has an established track record in Singapore and Hong Kong; however, there are extreme activity intensities around many stations in these cities and the development market is very savvy to the locational advantages of transit proximity. Furthermore, the Metropolitan Transit Railway Authority in Hong Kong, which operates the metro system, has significant development powers as far as permitting the leverage of value from transit orientation.

Parking Cash-Out Systems

By 2035, there will be a projected 1.7 billion vehicles on roads worldwide. As of 2007, there were already 254.4 million passenger vehicles registered in the United States alone, according to the U.S. Department of Transportation (DOT). The result of this burgeoning international fleet of vehicles can be seen in increased traffic congestion, accidents, and damage to roads.

Another result is a massive volume of vehicular emissions, which come in the form of exhaust system by-products, including carbon dioxide, carbon monoxide, nitrogen dioxide, and sulfur dioxide. These emissions are a leading cause of many common air pollution problems nationwide. Correspondingly, cities with significant amounts of traffic also typically have air quality problems such as smog.

State governments and businesses have expressed an interest in reducing those problems by attempting to reduce the number of cars used in home-to-work commutes. Their primary approach to this effort has taken two forms. One is to increase the funding and quality of mass transit in their area. The other is to provide consumer financial incentives, such as parking cash-out systems.

Basics

Many employees of businesses are offered free or subsidized parking by their employers. Particularly in crowded cities where public parking spots are quickly taken, this can be a notable benefit to employees who drive. At the same time, it tends to

have the unintended effect of encouraging employees to drive their own cars to work. After all, they are assured a good parking space each day and know that they will not be inconvenienced having to hunt for one. The net result is a higher number of cars being used, with the correlated emissions and pollution problems.

Legislators decided that a way to decrease the number of cars on their state's roads was to reduce employee car use through parking cash-out systems. These mandate that employers offer cash incentives for employees who give up their parking places. The hope is that employees who voluntarily accept these incentives will stop driving by themselves to work. Instead, they will take mass transit, such as a bus or a train, or carpool with someone. In cases where the cash-out system is adopted, there will be fewer cars on the road, achieving the program's objective.

Typically, employees who give up their parking spaces get the money for doing so on a monthly basis. This is most convenient for employers, because they can reassign those spaces to others or simply stop paying to rent them. However, there are some cases where the payments are daily, correlating to the number of days the particular employee did not drive to work. Although substantially less attractive to employers, this approach does still reduce the number of cars on the road.

Challenges of the Program

Historically, a key challenge to fully implementing this type of program has been a lack of enforcement. In states where it has been implemented, some employers fail to comply. With insufficient government oversight in place, the noncompliance of employers is rarely addressed by authorities unless there is a specific employee complaint.

Such complaints are rare for two reasons. One is that many employees want to drive their own cars, finding it to be the most convenient method of commuting. Because of that, they have no interest in giving up their parking space, regardless of any financial incentive to do so. The other reason is that commuting employees simply do not know about the program and, therefore, have not considered it as an option.

Employers, in turn, may make only minimal attempts to inform staff members about it. They may not embrace the environmental goals, or may

feel that subsidizing parking is a critical way to attract and retain quality employees. California has attempted to address this by making cash-out payments from employers deductible as business expenses. As would be expected, this improved tax treatment has increased business interest in the program, providing a blueprint for other states that try it.

California faces a separate challenge with the law, which is the fact it only applies to some businesses. Specifically, it applies to businesses that can immediately reduce their operating expenses by discontinuing the rent or lease of surrendered parking spaces. Those that can are able to quickly recoup cash-out payment costs, but not those that own their spaces or cannot stop renting spots on an individual basis.

Rhode Island

Parking cash-out systems are handled differently in Rhode Island. While California pioneered the program decades ago, the Rhode Island government has taken a unique approach to it. Under the state law 37-5-7.1, businesses that currently provide employee parking spaces are required to offer Rhode Island Public Transit Authority (RIPTA) passes as an alternative. A RIPTA pass allows commuters to take unlimited bus rides throughout the state. A replacement pass is typically issued at the beginning of each month, and each bus includes conveniences like bicycle racks. With frequent trips to most destinations, this can be an attractive option for many commuters.

Employers are told that active involvement in the program will help their public images because helping the environment is viewed favorably by many consumers. Employers are also told that they will save money, because the cost of a transit pass is less than the cost of a leased parking space. In cases where employers own the spaces, they may be able to convert those to use by customers, potentially increasing business and revenue.

Voluntary participation by employees is encouraged in a similar way by mentioning benefits, including saving money that would be spent on gas, helping protect air quality by having their car on the road less, and minimizing the stress associated with driving. Those who are motivated by such considerations may also choose to carpool, achieving the same effects. The government of Rhode Island

is aware of this and has set up park-and-ride lots offering free parking to carpoolers.

Additional Considerations

Although some employers have viewed subsidized parking spaces as a critical recruitment tool, their prospects in that respect can actually improve with a parking cash-out system. After all, not all employees want to drive their own cars to work. Some might enjoy carpooling for social reasons, or have a personal preference for riding mass transit. In these cases, they will want their chosen method of travel to be recognized and subsidized by their employer, just as driving is now. An astute employer can recognize this and communicate a desire to benefit all employees, regardless of their mode of transportation. By combining messages to employers and employees with greater publicity, parking cash-out systems are likely to become more popular in the future. Millions of commuters care about their impact on the environment and view mass transit or carpooling as a good way to help.

In addition, publicity about the availability of buses and trains helps the programs to do better. If commuters can feel more confident that a bus will get them to work on time, they will be more likely to take it. Businesses can also promote carpooling by designating special parking spaces for it and offering encouragement in meetings and materials. Ultimately, though, it will always come down to commuter choice. If commuters can be convinced that it is a good idea, they will want to be a part of it.

Parking Demand

Parking is an essential, though often overlooked, component of all transportation systems. Transportation systems may be conceived of as having two distinct physical components: a network of guideways, with vehicles that travel over that network, carrying passengers and/or goods. In this view, parking facilities represent specialized nodes along the network for storage and servicing of vehicles not in active use.

While the term *parking* usually refers to storage for automobiles and trucks, in infrastructure terms, vehicle storage also looms large in the maritime and air transport systems. The physical networks used by air and water transport are mainly supplied by nature, but the majority of investment apart from vehicles is in terminals (seaports and airports); berthing of ships and aircraft is an important component of such terminals.

Parking demand studies focus on cars and trucks for good reason. While the global maritime and aviation fleets are numbered in tens of thousands, cars and trucks number in the millions in most nations, and, in the United States, the motor vehicle fleet is nearly as great as the population. Moreover, compared to other modes, the average car is infrequently in active use.

In the United States, travel surveys reveal the typical private vehicle is in motion less than one hour a day. This means that more than 95 percent of the time, the vehicle must be parked. A typical automobile parking space requires approximately 320 square feet (30 square meters), including necessary maneuvering space, so the demand for parking space is prodigious in countries and regions where motor vehicle ownership and use is common.

The demand for automobile parking is a by-product of the demand for automobile travel. A motorist travels to a certain destination for a certain purpose (for example, to work or to shop) and must store the vehicle upon arrival. From the motorist's perspective, a parking space directly adjacent to the destination is ideal, and the desirability of a parking space decreases with the amount of distance, cost, and difficulty of reaching the nearest parking space to the desired destination.

Parking Demand Studies

Typically, parking demand has been studied in association with particular land uses (for example,

residential, industrial, and retail). After determining the nature, intensity, or size of the land use at a site, the number of vehicles parked at the site is surveyed. The objective of the survey is simply to count the number of vehicles parked at the time of peak parking demand; in practice, parked vehicles are often counted throughout the business day in order to determine when the peak period occurs. A side benefit of day-long parking surveys is that they give an indication of parking demand fluctuations throughout the day, which is important for determining the potential for shared parking, discussed further below.

A standard reference for determining parking demand is "Parking Generation," an informational report by the Institute of Transportation that provides parking demand ratios for more than 100 land uses and building types. "Parking Generation" is updated from time to time; the current edition, the fourth, was published in 2010. Most of the data in it are derived from surveys of single-use suburban developments with little or no significant transit ridership or ridesharing, and the parking facilities at these sites are typically reserved for the exclusive use of the traffic generated by the site, at no charge. At such single-use sites, the demand for parking will be high, given the convenience of the parking and the lack of alternative access modes.

As a result, analysts cannot directly apply such parking demand ratios in downtowns and other locations where there are close-knit, mixed land uses. Such rates will overstate parking demand significantly by overlooking the ameliorating effects of the motorist making several trips to different land uses from a single parking space, as well as the effects of transit usage, ridesharing, or other forms of traffic demand management possible in dense, mixed-use areas.

The process of developing parking demand for downtown sites and other complexes, and the process for isolating the demand for specific land uses in such environments, has yet to be standardized. In general, it requires surveying both parking space occupancy and turnover, and interviewing visitors about the number of trips made to individual establishments within the study area.

Shared Parking

Shared parking occurs where parking spaces are available for use by more than one land use or

establishment. Given the space intensity of parking and high value associated with developed land, from an economic standpoint, it is sensible for proximate land uses to share parking. In order for parking to be shared between two or more uses, one or both of the following must occur: (1) the parking demand of these uses must peak at different times; and (2) the land uses must be complementary, that is, some visitors to one land use are likely to visit the other via walking from the first use.

For example, parking demand for a cinema will typically peak in the evening, and so the cinema may be able to share parking with an office building, which peaks midday. A laundry in a mixed-use district may not need dedicated parking if most of its patrons are employees of nearby establishments.

Parking Demand and Parking Pricing

One of the challenges of setting parking requirements and designing access and parking systems is that parking generation and demand are not fixed; both depend on the price of parking. Many smaller cities and suburbs are planned on the tacit assumption that parking should be free to the user. However, parking is never free to the supplier. Typically, the land and construction costs amount to thousands of dollars for surface parking and tens of thousands of dollars for structured parking.

Charging for parking or increasing parking price reduces demand by shifting driver trips to other modes. Some demand may shift to other business districts and establishments that do not charge for parking, which causes resistance to implementing parking charges. It is important to realize that not charging users for parking does not eliminate parking costs, only that the costs of parking are socialized.

Cruising for parking represents another socialized cost of underpriced parking in congested downtown areas. Cruising for parking, defined as circulating near one's destination at low speed, looking for a parking space on the street, is motivated by a combination of preference for on-street parking (particularly if it is free or underpriced), and uncertainty about the existence and location of such a space. In larger downtowns at peak times, a large fraction of vehicular traffic and congestion is attributable to cruising for parking.

In conclusion, the need to park a vehicle requiring a large amount of space affects many aspects

of urban travel—the travel mode used, the destination chosen, the time of the trip, and how and if other trips are linked to the primary trip. Cruising for parking adds pressure to already congested networks as motorists seek difficult-to-find or cheaper parking spaces.

Given the complexity of motorist parking behavior, no unified method has been developed to fully model parking activities. To date, parking demand studies have often overlooked the effects of parking or the lack of pricing. In the future, pricing and traveler information systems promise to better integrate parking demand and choice with the demand for the trip itself.

Parking Design Requirements

There are more than 2 billion parking spaces in the United States, more than 85 percent in and around metropolitan areas with more than 25,000 in population. Parking design refers to the decisions—architectural, engineering, environmental, economic, and even cultural and social—that must go into constructing new parking spaces or converting

used or empty spaces into new parking spaces or devising regulations guiding the designation of particular streets or specific parts of streets for parking, decisions that must take into account a variety of factors including land usage, demographics, traffic volume, and pedestrian and traffic flow.

While municipal decisions concerning designing on-street parking impacts residents, visitors, and business owners, design requirements primarily involve the development and construction of parking lots. In major metropolitan downtown areas where more than a third of the available land may be given over to off-street parking lots (indeed, parking lots could be their own nation; across the country, parking lots consume more than 3,500 square miles, nearly twice the size of Luxemburg), urban planners consider parking design one of the most pressing (and neglected) issues facing contemporary cities.

Since the explosion in vehicle ownership after World War II, critics of the urban landscape have decried the intrusion of parking lots as a blight, a dead-end strategy in which cities cannibalize themselves, providing more convenient parking spaces to encourage people to come downtown, to make the lives of residents more convenient, or just to improve transportation to and from work or entertainment and sports events. But in the relentless determination to make mass parking available, cities have paved themselves over, surrendering to the asphalt look that creates an aesthetically challenged urban landscape, thus ironically driving away the very people—entrepreneurs, tourists, potential residents—they had sought to attract in the first place. That effect—the so-called Pensacola parking syndrome, named after the Florida panhandle city where the effect was first documented—measures the difficult challenges facing parking designers in the postmodern city.

Of course, city residents prefer private or on-street parking. Since the early 1960s, cities routinely required a specific ratio of cars to available parking spaces in and around housing units and retail sites. While mandating a steadily escalating number of spaces (or stalls) has done little to improve the visual aesthetics of a city, the limited availability of accessible parking spaces has created enormous friction among residents who must vie for accessible parking—ironically, urban planners have long argued that there is abundant space for parking in cities, save that drivers demand the closest possible

spaces, despite the obvious: parking farther away and walking actually saves time (and frustration) over driving around looking for more convenient parking. However, limited parking availability in cities has created a market for parking spaces—they are secured as part of housing agreements and can be owned and passed down through a family in a legal chain. Indeed, tandem parking spots, that is two parking stalls one in front of the other, most often in pull-offs from the street, are valuable commodities routinely bought and/or auctioned off, as they provide guaranteed parking for two cars.

Because local governments are now attuned to often vocal green objections to over-paving, designs for proposed lots routinely begin with gathering data about need, specifically the volume of vehicular traffic about a particular traffic generator, say a business or a mall or a sports arena, or a general assessment of a block or two of businesses, shops, and restaurants within walking distance of the proposed lot. Data is gathered on existing parking facilities, their location, the number of parking stalls, and the rates charged plus the time parameters to park there, as well as parking stall turnover. Based on this data, engineers project a specific number of parking spaces a new lot would need to accommodate using an elaborate mathematical formula to derive the probability of what is called “rejection,” those occasions when vehicles cannot find a parking stall. When the rejection number is high, engineers recommend constructing the new parking lot.

Parking design requirements work to maximize the number of available stalls without compromising the basic maneuvers drivers who are parking cars require. Indeed, parking design mandates designing lots that allow drivers to pull into the stall in one easy maneuver. The basic process for parking—entering the lot off the street, working the aisles looking for an available stall, entering the stall, exiting the vehicle, walking to the destination, returning and exiting from the parking stall, maneuvering to the exit, and returning to the street—guides the design requirements. In general, average-sized cars are allotted about 300 square feet of parking space in the traditional 90-degree stall, that is simply pulling straight in. That span is adjusted when accommodating special-assistance vans, in which case federal guidelines mandate a wider space for stalls. When parking lot design

A parking lot for a shopping mall in Gjøvik, Norway features traditional 90-degree spaces, wide search aisles, and extensive crosswalks. In parking design, average-sized cars are allotted about 300 square feet of parking space in the traditional 90-degree stall (pulling straight in). Special-assistance vans are provided a wider space, per federal accessibility guidelines.

puts cars at angles, most often 45 or 60 degrees, maneuvering in the lot aisles must accommodate that loss of space, most often by making aisle traffic one way.

Parking design also requires strategic planning of the lot itself. The entranceway to the parking lot, often positioned, much as the egress gates, in mid-block to avoid conflict with intersections, is usually designed to the specifications of a traditional double-width garage. The entrance and exit must provide the accessibility and user-friendly environment that public service spaces like parking lots need to provide; they are designed to minimize traffic holdovers extending into the flow of traffic on the adjoining streets. Similarly, because many lots require payment and hence must provide exit gates with stations, a rule of thumb for parking design is two exits for every one entrance.

The actual parking lot design must in turn take into account the dimensions of the individual

parking stalls, specifically, the needed width of the search aisles (based on a mathematical computation of the size of potential vehicles ranging from sports cars to minivans and sport-utility vehicles, the average stall size is 6 feet by 18 feet); the angle of parking desired (straight in or at angles, the most familiar being the interlocking herringbone pattern, stalls each at 45 degree angles in which the bumper of one car abuts the fender of another, but other parking designs put cars at angles of 60 degrees allowing for considerably tighter spaces and, hence, additional vehicle volume); and the total radius sweep necessary to allow vehicles to execute search maneuvers such as turning (aisle width is most often 18 feet).

The reality is that the increasingly limited available parking space in urban environments demands mathematical precision in designing lots and in weighing decisions about designating street parking. There is an evident imbalance—at once

too many spaces and too few spaces. Given that now in America there are three parking spaces for every one car, parking design protocol is ripe for radical reform.

Parking Finance

Managing financial policies and strategies to provide for and support parking capacity in a range of urban and nonurban environments is a very large and pervasive challenge for city planners, one that involves transportation authorities at the state level as well as federal administrators from a range of agencies. While many localities are burdened by somewhat antiquated parking requirement statutes that effectively hamper both public and private real estate development and deter quality-of-life improvements, more and more planners are discovering new ways to define parking-space requirements. At the same time, they are employing new types of financial instruments, alternate revenue structures and sources, flexible budgetary considerations, and diverse funding channels to support their 21st-century parking infrastructure and operations.

Automobiles are, on average, inactive at least 95 percent of the time. In other words, cars are seldom not parked. It is not surprising, then, that parking is an approximately \$30-billion industry in the United States, according to the International Parking Institute (IPI).

Although there are signs of transition away from a dominant car culture on many fronts, such as some movement to other modes, the fact remains that if planners do not work the parking of cars and access by automobiles into their intermodal schemes, the odds for overall success are reduced. In many cases, parking makes other modes work, because most nonautomotive travel and transportation modes generate the need for automobile parking.

One example is the case of the Bus Rapid Transit (BRT) system in Pittsburgh, Pennsylvania, which inaugurated its first busway in 1977 and has been expanding periodically ever since. The most recent five-mile West Busway sector opened in 2000. Its use at first lagged that of the other routes, but city planners predicted the additional availability of 2,000 parking spaces would galvanize ridership almost instantly. Their confidence was based strictly on real-world experience; they had built thousands of parking spaces in park-and-ride centers sited near the other busways. Similar experiences are recounted in places as diverse as Ottawa, Ontario, and Milwaukee, Wisconsin—where more than 30,000 parking spaces were deemed vital to the launch and success of its Transitway Plan of 1990.

Development and Flexibility

The space necessary to meet municipally required parking accommodation for real estate development in many jurisdictions can average roughly half of the available project space. This dominant feature means that decision making on the parking issue can substantially determine the size and scope of financing needed to enable a given development to proceed or to stall out.

In real estate development, a general rule is that the lower the number of required parking spaces, and the lower the cost of those spaces, the lower the project development costs will be as a whole. Land costs and complex site configurations are additional factors. These are all rather direct matters to comprehend and to incorporate into development planning.

The financial return side of the development equation, however, tends to be less predictable than the cost side. The core factors include the amount of marketable space, occupancy rate, and rental or selling price of the space. Plotted against these variables is the balancing of parking as an amenity against parking as a consumer of space that could be otherwise be developed to expand the liveable

or ancillary attraction space of a project—in other words, space that may or may not be worth more in a nonparking use.

Lenders who are sensitive to local heritage, legacy, and lifestyle issues are typically more likely to expend political capital in working with municipal authorities to find alternatives to the strict application of existing parking statutes. City leaders, for their part, might also be willing to see the bigger picture, as was the case in the development of Circle Centre in downtown Indianapolis, Indiana, in 1995. To solve the parking challenge of this \$300-million mixed-use development, the city, the developer, and other local constituents were able to fashion a shared-parking plan. In this case, rather than constructing the 6,000 new parking spaces that would technically have been required, the developer was permitted to build just 2,815 spaces.

Two shared-parking factors went into this decision. The mixed-used nature of the project meant that a single parking space could be utilized by customers for multiple destinations within the project, with different flows at different times of day. Further, there were 12,000 existing off-site parking spaces in the vicinity available for Circle Centre employees and visitors to use, especially during off-peak times. These two factors altered the fundamental math of the situation, revealing that less than half the required-by-statute 6,000 on-site parking spaces would be necessary. The net result was a development cost reduction of some \$30 million, as well as a cut of about \$1 million in annual operating costs. The financing of the project was more readily attained under these circumstances.

Municipal Options

Often, a municipal planning body perceives its choices on parking development as confined to simple decisions, such as whether to invest in surface, structured (above-ground garage), or underground facilities. Knowing the cost of an underground facility can range to approximately twice the amount per space of an above-ground or structured garage—and that surface lots cost only a fraction of that—tends to form the core “given” in such decision-making processes.

Another core tenet is that, rather than determine to build and operate a garage itself, a city or similar body can elect to lease from a developer, potentially freeing itself from much of the

financing decision making and responsibility it would otherwise be liable for. Still, a private developer may very well insist that the city share the financing burden through a bond issue. A developer may also negotiate tax deferral or tax reduction for a number of years as compensation for taking on the responsibilities of construction. The city, therefore, must prudently consider how the revenue streams from parking fees will be divided between itself and such a developer.

In any event, several types—at least three main categories—of beneficial constituents must be considered beyond the developer. These constituents include the parking facility users; the merchants, other property owners, and businesses within walking distance of the facility; and the general municipal area itself. All stand to benefit. To the extent that this can be predicted and demonstrated in clear fashion, substantial revenue from each category of parties can be reasonably expected, without too much in the way of political objection.

One typical contributing funding mechanism based on this principle is a business-improvement district or local property-improvement-area designation, which would allocate various portions of cost to those locally benefiting. Such funds are used to retire bonds and, after that event, to defray operating expenses.

Public–private partnerships of this type are often established to inaugurate and operate municipal parking structures and systems. They generally prove integral to success.

For example, in Kirkland, Washington, the city Parking Advisory Board recommended a financial plan that would (1) commit to price on-street parking to gain reliable levels of local user payments by way of a pledge for retirement of parking revenue bonds for a portion of the city’s share; (2) set up a local improvement district containing properties within walking distance of the new public parking supply, to be actuated when bonds are sold in order to finance a portion of the cost; and (3) include new parking supply in the City of Kirkland Capital Improvements Program, “to be financed from general revenue and/or traffic impact fee bonding.”

A plan was devised consisting of parking revenue + business dues + taxes and fees = bond payments for the capital investment needed to satisfy the city’s parking finance needs. This benefited all

parties, and the plan of spreading the risk was a factor in gaining more favorable borrowing terms.

Hidden Revenue

There are hidden financial streams in some already installed parking systems. The city of Tampa, Florida, for example, discovered that replacing outdated lighting in its parking facilities cut its expenditures for electricity in half. This yielded a direct and recurring financial benefit to the city. In Los Angeles, city leaders were able to partner with private development interests in order to execute a planned upgrade of parking meters at no cost to the city—and generated revenues that funded additional new equipment.

In San Francisco, without adding a single new parking space, the city uncovered new revenue by maximizing the use of its existing parking capacity. The SFpark pilot program deployed federal congestion-mitigation funding to test a demand-adjustable rate system for on-street parking in several districts of San Francisco. The success of the program led to a similar federally funded project in Los Angeles, dubbed LA Express Park.

Projects in these cities and elsewhere are increasingly tapping the potential of wireless technology to aid drivers in identifying parking space availability, as well as to pay for parking by mobile device. This simple solution holds major promise as a dramatic means of cutting cost while increasing parking utilization to capacity, thereby unleashing otherwise forgone revenues—and, in essence, providing an alternative to the need to seek and be bound by additional financing and debt.

The federal government can be a vital source of direct funding for some types of parking solutions. For example, within the framework of the Moving Ahead for Progress in the 21st Century Act (MAP-21), enacted in 2012, the Surface Transportation Program provides an annual average of \$10 billion in flexible funding that may be used by states and localities for projects “to preserve or improve conditions” in a wide range of public transportation facilities. Among these facilities, a variety of parking and parking-related infrastructure types are specifically enumerated. These include truck parking facilities, electric vehicle charging infrastructure added to existing or included in new fringe and corridor parking, electronic toll collection and wireless electronic-funds-transfer-enabled

smart-meter systems, and parking areas connected with mass transit stations and terminals.

Self-Funding Ideal

Institutions other than municipalities have learned to utilize parking as operations that can be—at least in part—self-funded. The University of Tennessee (UT) in Chattanooga, for instance, generates parking-related revenue from decal sales, tickets and fines, visitor passes, event revenue, its main parking garage, and a sales tax. The system typically generates a modest surplus of revenue on an operating basis, but it has lost money when capital investment or major new expenses are factored in. The wild card is that UT students control the parking financing, and this means each new wave of students must be made aware of the underlying costs and financial strictures of the system that provides parking convenience to them.

Environmental concerns can contribute to financing options in support of parking capacity, in a sense providing an additional measure of self-funding. Employers in California have availed themselves of one such option, the Parking Cash-Out program. This is a scheme conceived to mitigate some of the very real and, in California, exhaustively quantified costs of reliance on the automobile for commuting, and the resultant highway congestion (for example, environmental and health cost, lost productivity, road wear, enforcement and first-responder personnel and systems cost). Under Cash-Out, employees who opt not to use private on-site parking at company work locations receive a cash payment. This incentive has the net effect of actually relieving pressure in other parking areas, because the cars these employees would have driven now stay home in their private spaces.

Limits and Capacity

Some planners and policy makers look at city centers and perceive an oversupply of existing parking and parking-adaptable brownfields (underutilized or outdated structures and neighborhoods). This perception can have various financial implications when they are considering the development of new mass-transit systems, and, in particular, the transit-oriented development (TOD) that accompanies any planning for the construction and activation of local stations to support intercity rail, subways, monorails, bus rapid transit, etc.

TOD goes hand in glove with city center marketing and urban core redevelopment, a powerful trend over the last several decades. The competitive environment both within and between city neighborhoods means that parking has become a more significant bargaining chip in these cases. Light rail and commuter rail stations, as examples, are often designated as either feeder stations or destination stations, which results in different manifestations of TOD projects.

Feeder station areas are typically residential or suburban areas that often have TOD projects, including neighborhood restaurants, cleaners, and grocery stores. As such, these stations are usually less dense and have park-and-ride lots.

Destination stations, most often sited within the central business district or near major entertainment venues or government centers, tend to foster high-density TOD that can include mixed-use housing, office complexes, stadiums, arenas, and other entertainment facilities. TOD around these destination stations usually does not have park-and-ride lots, and they are typically located in areas with few parking spaces. In an effort to reduce automobile congestion and create more space for TOD commercial and residential development projects, many cities have modified zoning codes to effectively lower the required number of parking spaces in areas adjacent to these stations. This, however, raises the value of any nearby parking facilities, tips the pricing dynamic in sometimes unpredictable ways, and alters the calculations for the financing of parking in the TOD area.

Parking Generation Rates

It is anticipated that most land uses will generate or attract private vehicle trips. Thus, to support access to individual developments, parking needs to be supplied. Consider the case for a residential development, where parking supplied in association with the development generates private vehicle trips. Accordingly, when parking bays are supplied with residential units, tenants are incentivized to own a private vehicle and to use that private vehicle for trips. Parking associated with nonresidential development, such as offices, attracts private vehicle trips; that is, it induces tenants and visitors to drive to the land use.

Conventional Calculations

Conventional planning practice is to supply parking on the assumption that individual land uses generate or attract stand-alone parking demand. That parking is typically supplied in accordance with a defined set of criteria based on known parking demand associated with comparable existing land uses. Plainly, the scale of development has a bearing on the parking requirement, and this is another variable for consideration in calculations of parking supply.

Standardization of parking supply in these ways has been aided through the preparation of manuals such as the Institute of Transportation Engineers' "Parking Generation" report in the United States and the New South Wales Roads and Traffic Authority's "Guide to Traffic Generating Developments" in Australia. These and similar manuals have formed the basis of planning scheme requirements for parking associated with new developments, which are applied by approval authorities. These requirements are generally expressed as a number of bays provided on-site per unit of development; for example, bays per dwelling unit or for each 100 square feet or meters of gross floor area.

Common practice is to specify a minimum but not a maximum parking requirement. This is because application of a minimum is perceived to minimize the risk of parking overspill, and therefore the use of bays not specifically intended for use by people associated with a defined land use. In contrast, maximum provisions are not considered to serve a particular planning purpose. Furthermore, some developments may be considered to have a competitive advantage in supplying a generous amount of parking, as this can be attractive for tenants and visitors. These perceptions are changing, though, and are explored in further detail below.

Plainly, application of standardized formulas for parking supply has provided development proponents with a degree of certainty regarding the amount of parking that they should provide. Moreover, it has simplified the process of evaluation by approval authorities, who can simply check whether or not a development conforms to requirements. However, the survey data that underpin the formulas have a number of shortcomings, which can lead to parking supply for a particular development not being responsive to context. These shortcomings include the following:

- Survey data relating to a limited number of sites, meaning the data set is not very powerful
- Survey data having been collected in a unique context, such as suburban locations where land uses are atypically car oriented
- Assumptions that the users of parking are actually visiting the land use that it is associated with
- Reporting parking requirements based on a high percentile period of demand, and only for particular periods in a day (that is, during ultra-peak periods of activity, such as the Christmas shopping period for retail)
- Limited sampling to reflect peak periods, parking accumulation over time, or seasonality of the particular land use

In addition, survey data can be a useful reference for relatively common land uses, such as office or general retail. However, a benchmark for parking supply can be much more difficult to establish for mixed-use or boutique and less common land uses, simply because there are much less survey data (and, therefore, standard requirements) available.

Analysis of Stand-Alone Requirements

In practice, the stand-alone parking demand associated with individual land uses depends on a variety of different factors, and a sound understanding of the urban context is needed to understand specific supply requirements. Relevant land use and transport variables include the following:

- The extent to which user groups—visitors, tenants, residents, and so on—can access the subject land use by modes other than private vehicle. Plainly, this is a function of public transport service provisions, and the walkability and attractiveness for cycling of the built environment.
- Constraints imposed by the local road network, which can either dissuade or limit people from driving to the subject land use.
- The land uses that are nearby, adjacent to, or integrated with the subject land use, as a portion of trade may be "passerby" and not

require stand-alone parking supply. Excellent examples of this are found in town centers and mixed-land-use precincts where a high percentage of trade associated with boutique retail and cafés may be generated by local residences and office developments.

- Effects of trading hours and variable-demand profiles between different, clustered land uses. For example, office developments can generate parking demand within standard business hours, whereas a nearby restaurant may experience heaviest trade and, therefore, parking demand in the evening and on weekends. Under these circumstances, it is much more efficient for at least a portion of parking supply to be shared between the different land uses, based on analysis of when overall demand for parking across the respective developments is at its peak.
- The availability of public parking supply in the area, including on-street parking, because this can offset at least some of the independent parking demand associated with land uses.

Researchers including Donald Shoup, G. B. Arrington and Robert Cervero have highlighted the problems associated with using standardized parking supply rates to stipulate requirements for proposed land uses. Their research has shown that developments within town centers and transit-oriented developments (TOD) require significantly less stand-alone parking supply than equivalent developments in low-density suburban locations. This is for the reasons specified above.

The researchers posit further that oversupply of parking, aside from being spatially inefficient and an unnecessary cost, can induce private-vehicle trips and undermine motivation to use alternative modes, such as public transport, walking, and cycling. This constitutes a poor outcome in a town center or TOD.

Contextually Specific Calculations

While the intricacies of calculating real parking needs are increasingly well known, the resources required to assess stand-alone parking supply requirements and determine a management regime

can be considerable. This tends to present difficulties for approval agencies—especially local governments—that often rely on standardized processes for managing development applications and may not have the necessary skill set to assess each application on its own merits.

On occasion, the development proponent may not be equipped to adequately account for context in defining a reasonable amount of stand-alone or shared parking supply. This is most evident when there is little or no precedent to which to refer, which is more likely when the proposed development is more specialized.

Special Uses and Considerations

There are land uses that attract extraordinary trips, and, therefore, require a bespoke parking-supply strategy. Depending on the special land use, which may be a one-off or irregular event such as parking associated with a concert venue, independent parking supply may be inefficient and undesirable. Sports stadiums provide one example of a use where a highly independent parking supply may be considered desirable, even though it is used infrequently.

In contrast, while weekend farmers' markets in a community may be equally infrequent and as large a generator of parking demand, planning authorities might not consider the markets to warrant independent parking supply. Under these circumstances, temporary parking may be accomplished within open space, with some parking spilling over onto nearby streets and public parking facilities. Some visitors may also attempt to park their vehicles within proximal private parking facilities. This may require institution of a management regime.

Strategies to Justify Reduced Supply

Fees and other regulatory strategies may be employed to help justify reduced rates of parking relative to conventional standards. This is on the basis that these mechanisms help reduce vehicle trip demand and therefore demand for parking. For example, there are well-established parking price elasticities in the literature, and many practitioners would agree that an elasticity between 0.1 and 0.3 would be reasonable to assume. This means that a 100 percent increase in parking fee may lead to a 10 to 30 percent reduction in demand for parking.

Similar parking demand reductions are possible through institution of dwell-time limits. For example, capping permissible dwell time at two hours will help avoid demand for parking by commuters, although such regulations require enforcement to be effective. Pricing and dwell-time limits are not practical for residential land use. This is because tenants have a reasonable expectation to be able to use a bay assigned to their unit when they want to. As an alternative, parking bays can be unbundled from the sale or lease of units, thereby providing tenants with the choice of whether they need or want to buy or rent parking spaces. Unbundling is commonly considered to be an economically efficient method to reduce parking investment for developers, even though it is a relatively unconventional practice.

In general, the complexity of a parking supply and regulation will depend on where a development is located within an urban environment. Reduced parking supply relative to conventions may only be reasonable where residents, workers, and visitors can access alternative means of transportation to offset the reduced supply of parking. These alternatives need to be realistic: for example, they cannot mean significant additional travel time and cost. Otherwise, the commercial appeal of a development can be compromised due to low accessibility.

Parking Lots

Parking lots are designated areas where it is permitted to leave personal vehicles in a comparatively safe location, generally for a fee. The level of the fee and the expectation of the length of stay will generally be dependent on the location and purpose of the parking lot. Those that are attached to out-of-town shopping malls, for example, exist to encourage people, especially families or groups, to visit for extended periods, and so fees will be low or even free. Parking lots attached to train stations, meanwhile, are aimed at providing a service for people to return after a number of hours, for example, as part of a daily commute, and so fees are structured so as to be convenient for regular users.

Parking lots may also be used to organize the movement of people within cities or at tourist destinations by gathering vehicles in certain locations so that people can be moved by a form of mass transit for organizational or environmental purposes. In other words, parking lots can have various purposes in addition to the basic one of housing vehicles.

Purpose and Location

In urban areas, in particular, space is at a premium, and if vehicles can be parked along the curbs of streets, traffic may become clogged. This leads to problems with pollution, safety, and inefficient use of time because people find it difficult to find a space near their destination. In some cases, people will be tempted to park illegally or to double park, which will exacerbate the problems for all drivers in the area. Clearly, therefore, it is important for urban planners to ensure that appropriate parking space is provided for residents and visitors. Limited on-street parking space can then be retained for emergency services.

Because urban space tends to be very expensive, it is important to minimize the amount of space occupied by each vehicle. This is generally approached through employing multistory structures and basement designs, both of which can be efficient uses of space. In Singapore, for example, a large proportion of the department stores and malls have extensive basement parking lots that use computerized signage to alert drivers of how many vacant spaces are available on each level and, with a system of green and red lights, exactly where on an individual level a vacancy exists. Regardless

Many of the vehicles in this parking lot at the Cincinnati Zoo in Cincinnati, Ohio, in May 2013 are shaded by a roof made with solar panels; the electricity generated by the panels is used to help power some of the zoo's other facilities. In developed countries, parking facilities are making use of similarly innovative technologies to contribute toward sustainable energy use, while others are using new technologies to reduce labor costs, such as mobile telephone payment systems.

of Singapore's extensive public transportation network, the use of personal vehicles is still popular in the country, especially for family outings and shopping or leisure trips. These trips are more expensive and are regulated further by the use of electronic ticketing during peak-hour traffic periods. The central retail area would quickly become overrun with traffic without such advanced management systems.

In other places, such as in the United Kingdom (UK), it is possible for commercial companies to run parking lots as profitable concerns. This is particularly true in larger cities such as London, where many destinations have no parking spaces attached, and, consequently, visitors are willing to pay quite large amounts of money to be able to take their vehicles with them. This includes service workers, such as plumbers and electricians, who have extensive suites of tools and equipment they need to take with them on calls.

London is a historic city, and much of its development took place at a period when horses or horse-drawn vehicles were the principal mode of transportation. As a result, thoroughfares are narrower than cities developed in the modern age, and there may be important buildings and facilities located in difficult-to-access sites. In areas of particular historical interest, it may be impossible to redevelop the land uses, and so consideration needs to be given to organizing orbital parking lots or imposing pedestrian-only areas for visitors.

In the case of the university town of Oxford, also in the UK, orbital lots are placed at the junctions of arterial routes and the outskirts of the city, and low-cost and frequent buses are available to take the visitors to city-center areas where walking to different locations is quite convenient.

Such precautions are not generally required in cities more recently planned with automobile use in mind. In the case of countries such as the United

States, space in certain cities is not so constricted, and many land uses are able to maintain their own parking facilities.

Many Americans associate the use of their personal vehicles with a sense of freedom and individuality, which has tended to militate against the successful use of public transportation, at least outside the major cities. Suburban and rural life takes place in an environment in which space is more plentiful, and most homes have scope to accommodate one or even several vehicles. In these cases, parking lots are needed at retail or commercial premises to accommodate the vehicles that are necessary to travel there.

Design and Safety

Parking lots can sometimes be dangerous places because they may be open late at night, are easy to access, and offer many places for potential assailants to hide. People walking in parking lots at certain times are vulnerable to personal assault and robbery or attackers wishing to steal their cars once drivers open the doors. In lots in remote or under-observed areas, vehicles may be subject to theft or breaking and entering. Operators of such facilities provide various safety features, such as closed-circuit television systems, alarms, or on-site guards to provide people with sufficient confidence to use them.

For safety and convenience reasons, some parking spaces must be reserved for people in certain categories, especially people with physical disabilities, close to the entrance of the facility. Some lots may offer spaces for dropping off passengers near entrances, which are sometimes known as kiss-and-ride areas.

Because there is a likelihood of wheelchairs or similar equipment being used, spaces designated for people with disabilities will be larger than usual. Space size also varies because of sociological and geographical reasons. In some countries, average car sizes consistently tend to the smaller (for example, Japan) or the larger (for example, the United States) and this has an effect on the space required.

In most of Australia, housing space is relatively abundant and most families have large kitchens and fridge-freezers. This, in turn, leads to the need for large supermarket carts and, hence, greater space required in the parking lot. In situations in which space is constrained, large vehicles may be charged extra or banned from entering.

Payment Systems and Value-Added Services

Parking lots routinely require users to pay for their use, either directly or indirectly, and there must be some system to ensure payment is made. Simple systems include a manned cubicle monitoring entry and exit points. Customers are issued a ticket on entry and then surrender it when they are leaving. Manual or electronic systems determine the length of time that the vehicle has been parked, and, consequently, how much the fee should be.

In countries with comparatively low labor costs, large parking lots may have quite substantial complements of staff. However, people have been replaced by technology in most developed countries. In these cases, an electronic barrier prevents access until a token or keycard is taken or used, and, before leaving, drivers must pay by cash or credit card at the payment machine. Newer payment technologies include mobile telephone payment systems.

The prevalence of reliable mobile telecommunications and comprehensive Internet and network access in many developed countries has meant that previous forms of payment systems, such as coin-operated clockwork machines or pay-and-display systems are becoming obsolete. Similarly, the job of parking meter attendant—a person who patrols an urban environment checking whether vehicles have exceeded the permitted length of stay and issuing penalty tickets when necessary—is also being phased out in favor of technological solutions. However, in most parts of the world, this level of technology is not available, and less efficient manual systems remain in use.

In some upscale department stores and shopping malls, parking lot management may offer a valet-parking service, which means staff park the vehicle for the driver, for a fee, and retrieve it later when the customer is ready to leave. This saves time for the customer, who might otherwise have to spend a considerable amount of time circling around waiting for a space. Valet parking can also provide the most efficient use of existing space because valets can use skillful parking maneuvers and venture into dark or remote locations ordinary customers would not always be happy to use.

Valet parking is one of the more obvious forms of value-added services that can be offered at a parking lot that improve attractiveness for customers and profitability for the lot operator. Another service is automobile washing and care, often provided by a

subcontractor leasing space in the lot and cleaning vehicles while customers spend time in the adjacent facility. In very busy cities such as Bangkok, the car cleaning area may be the only part of the lot that has any vacant spaces.

Particularly in urban space in developed countries, providing parking lots sufficient to the needs of an ever increasing population represents a significant expenditure of resources. Certain critics have noted that easy and free or low-cost parking encourages people to own and use personal vehicles rather than mass transit, walking, bicycling or shared-transport options. This results in additional pollution and street congestion. Making conditions convenient for automobile users often makes conditions less convenient and less safe for other road users, including cyclists, pedestrians, operators of mobile vending trolleys, emergency vehicles, and so forth. This is not necessarily an egalitarian solution.

Parking Planning and Management

Parking management is a critical responsibility of local transportation policy shared between public and private actors. Parking is one of the few transport policies that are under the direct control of

cities. Managed effectively through regulation and pricing, parking can improve traffic flow, enhance the pedestrian environment, encourage transit use, and raise revenue for public investment. In recent years, cities have experimented with innovative ways to improve the performance of their parking systems, but parking remains a largely unexplored area for transportation and land use planning. Therefore, it represents an extremely promising area for improving transportation demand management, increasing the quality of the built environment, enhancing nonautomotive modes, and raising revenue for public investment.

Parking can broadly be defined in two categories: off-street and on-street. Most off-street parking spaces in the United States, and much of the off-street spaces around the world, are required by minimum parking requirements in zoning codes. The public justification for regulating the supply of parking focuses on the false idea that parking supply should accommodate unlimited demand. In order to prevent spillover parking—where drivers park in residential neighborhoods when visiting nearby businesses—cities started to require on-site parking for all land uses and developments beginning in the 1940s. These minimum accessory parking requirements were quickly adopted by cities throughout the United States and around the world.

Off-Street Parking

Local zoning codes regulate the supply of off-street parking. It is very common, and nearly universal in the United States, for cities to enforce minimum parking requirements for all types of land uses. A typical residential requirement is one parking space per bedroom or one parking space per unit. For commercial properties, the requirements vary substantially, but three parking spaces per 1,000 square feet (93 square meters) is common. In most cases, parking required through the zoning code or use permits must be accessory spaces, or located on-site. The steady expansion of required parking has left urban and suburban cities with massive oversupplies of parking spaces, and most of these spaces sit empty most of the time.

Required parking increases the cost of goods and services for everyone, regardless whether or not they drive. By requiring parking on-site, the cost of building and maintaining parking is bundled in retail prices and rents. Researchers have

demonstrated how parking requirements increase the cost of housing, which is a major concern for affordability. Basic fairness is challenged when low-income families who are unlikely to own a car must pay for an abundance of parking they do not use.

On-Street Parking

While traditional parking management has focused on the supply aspects of parking, recent experiments have shifted focus to the role of prices to manage demand. Consider the case of street parking. Whether street parking is free or metered and paid, motorists often think that there is simply not enough of it. More accurately, there is excess demand for parking when the price is too low.

When all parking spaces along the curb are full, any drivers who want to park are “forced” to drive around searching for a space. This is known as “cruising for parking,” and many studies have estimated that in some neighborhoods drivers cruising for a space can represent as much as 40 percent of total traffic. Driving around looking for a place to park is excess travel once drivers have already reached their destination. Cruising for parking is a failure of the commons, where no one manages the spaces for the greater good. In a commons, many people acting in rational self-interest leads to overconsumption and overall costs to society. In this case, the individually rational action of cruising for parking causes tremendous damage to the environment, traffic congestion, street safety, and effective management of local transportation systems.

Municipalities are able to regulate prices of parking to promote occupancy rates. Unlike a coffee shop or restaurant, where customer turnover is a sign of success, properly priced parking achieves occupancy targets. However, what motorists really want is cheap or free parking, and there is ample evidence that they are willing to drive astonishing lengths in order to find a space that is just right. A review of cruising-for-parking studies suggests that in many urban neighborhoods, the share of traffic just driving around looking for a place to park averages around one-third of total traffic.

Theory

Theory predicts that cruising for parking is the result of underpriced curb parking relative to demand. Once drivers reach their approximate destination, they have the option of parking off-street, usually in

off-street spaces developers are required to build, or searching for a curb space. In areas where the cost of off-street parking exceeds that of on-street, drivers have an incentive to cruise around to find a space. Drivers will cruise for a space until they either find a space or their marginal value of time equals the money saved by parking on the street. In the latter instance, drivers will either choose to park off-street or abandon their initial trip destination. Under these circumstances, if the price of curb parking is raised to equal or exceed the cost of off-street parking, drivers will have no incentive to search for parking.

The elasticity of demand for parking is dependent on factors beyond parking location. Studies demonstrate that the demand for parking varies by time of day, perceived safety, weather, and other aspects. While many businesses and drivers voice concerns about the economic effects of increased parking charges, there is no scholarly evidence that suggests that parking management has negative influence on local economic activity. To the contrary, the few cities that have raised the price of parking have realized increased economic activity. This is especially true in places where the additional revenues raised from increased parking charges are used to improve local public services in the affected neighborhoods. Examples of public services paid for with meter revenue include public safety, sidewalk cleaning, trash removal, and other similar improvements.

Evidence

Managing the curb to maintain occupancy targets of one open space per block, or 85 percent occupancy, is recommended in the literature and called performance-based pricing. Many cities are using these standards in practice. In San Francisco, the U.S. Department of Transportation sponsored a project through its Value Pricing Pilot Program to evaluate how well prices work to manage demand for parking. The project, called SFpark, used seven pilot zones where sensors monitored the occupancy of curb spaces. Then, every six weeks, the city used the collected data to adjust the price of curb parking higher if occupancy exceeded 85 percent, or lower if occupancy fell below 85 percent. During the initial pilot test periods, the price of parking increased in some areas and declined in others through an iterative process of trial and error.

The city of Seattle, Washington, has also used prices to manage parking demand. In 2011, Seattle

used data from parking pay stations to adjust parking rates. Researchers studying the effects of the Seattle project found that drivers' sensitivity to changes in the price of parking vary by time of day. Lunch hours, for instance, feature the highest parking demand and require different pricing strategies than other hours of the day.

Contracting

In recent years, many cities have contracted out their parking-meter management in exchange for up-front payments. In 2008, the city of Chicago leased 36,000 street parking spaces for a 75-year term, in exchange for an up-front payment of \$1.15 billion. The city now features some of the highest meter-parking charges in the nation. While the merits of such privatization deals are contested among scholars and public officials, other cities are exploring these types of contracts to monetize their parking resources. From a traffic perspective, higher meter rates are desirable for reducing cruising and making other modes more attractive.

Conclusion

Parking management through pricing and regulations offers cities tremendous opportunities to shape and reshape communities. Minimum parking requirements are perhaps the most pernicious aspect of transportation systems, because they steadily increase the supply of parking without respect to demand or need. By flooding the market with required parking, cities ensure that driving is heavily subsidized, even by those without cars.

Excess off-street parking supply is made worse through underpriced curb parking. Meters that are too cheap or, as in many cases, free cause excess driving while motorists look for curbside spaces, even if off-street parking is available nearby. To better manage their parking assets and raise revenue, many cities are considering contracting the management of street parking to private companies. These contracts are often unpopular with the public, though, and need to be carefully drawn.

Curb parking is also heavily regulated, but it is often given away for free or close to free. Underpriced curb parking leads to excessive cruising around to search for a place to park on the street. This cruising distracts drivers, congests traffic, harms the pedestrian and cyclist environments, and wastes time. Ultimately, underpriced curb parking

also represents lost opportunity to raise public revenue that can be used for valuable public services.

Parking Regulation and Enforcement

Government has created parking regulations to keep streets in good order, secure roadways for emergency vehicles, protect public safety, and ensure the efficient use of this often scarce resource. Such measures include requiring drivers to pay for parking; prohibiting them from occupying one space for too long, reserving places for certain drivers or vehicles (for example, residents, disabled drivers, electric vehicles, etc.), or barring drivers from leaving their vehicles in certain locations. Although these regulations apply mostly to public parking, laws also exist to protect private parking spaces from being usurped by drivers who do not have the permission of the property owner to occupy an off-street space.

Despite the fact that parking laws usually have a rationale that withstood public scrutiny before enactment, there are always drivers who do not respect parking regulations—out of either negligence or willful disobedience. Parking enforcement is therefore designed to ensure drivers respect the laws by allowing the appropriate authority to sanction the drivers (or vehicle owners) who fail to comply with the law. While many drivers act in accordance with parking regulations, other drivers comply only with the threat of punitive action—either through

the act of being publicly reprimanded or sanctions that cause substantial inconvenience and/or financial damage.

Enforcement Mechanisms

Parking enforcement mechanisms vary by purpose. Some jurisdictions allow parking and law enforcement officers to give written warnings that carry no financial penalty. The more commonly used tool, though, is the issuance of parking tickets or citations to penalize an owner of a vehicle that is parked illegally. Parking enforcement personnel have the legal authority to issue tickets to motor vehicles, which they usually leave under a windshield wiper of a vehicle.

These tickets record identifying features of the vehicle (for example, license plate, make, model, and color), the violation(s) that merited the citation, and the date, time, and location. The citing authority also typically mails a copy to the address of the vehicle's registered owner to ensure a proper notification of the citation. A responsible party is required to pay the fine or can bring the case to a court for resolution.

The monetary fine of the citation must be high enough to dissuade most drivers from parking illegally. While this amount is sometimes determined arbitrarily, based on whatever amount sounds punitive yet politically acceptable to the officials responsible for enacting parking regulations, more methodological approaches do exist.

In the case of paid parking, for example, fines can be set by dividing the hourly price of parking by the probability that a violating car will receive a ticket within one hour. If the price of curb parking is \$3.60 per hour and the hourly probability of being caught is 2 percent, the fine is \$180 ($\$3.60/\text{hour} \div 0.02/\text{hour}$). This method is designed to have drivers eventually realize that getting a citation is less desirable than just paying for parking in the first place, either because the fine is very high or because they are very likely to get a ticket.

Public officials can also increase the likelihood that an illegally parked car will receive a citation by increasing the number of parking enforcement personnel. Many responsible agencies may find increasing staff too costly, especially if the revenue from parking fines does not cover the cost of enforcement. Alternately, an agency can increase the productivity of personnel by, for example, switching

from hand-written tickets to electronic handheld parking ticket printers that speed up the process of issuing tickets. Some parking enforcement authorities also use vehicle-mounted camera systems in conjunction with license plate recognition to issue citations. Speeding up the process of issuing tickets allows enforcement personnel to cover more ground, thereby increasing the probability that a scofflaw driver will receive a parking violation.

Some parking violations require more immediate remedial action than ticketing. Parking enforcement personnel often have the discretion of towing vehicles deemed a threat to public safety (for example, parked in a traffic lane, or blocking a crosswalk or fire hydrant) or that are appropriating spaces reserved for certain drivers, such as disabled people.

Drivers who chronically do not pay their parking tickets may also have their vehicles impounded. Impounded vehicles are usually brought to a tow truck company's property or a public tow yard, where vehicle owners must go to retrieve their vehicles. Drivers must often pay high administrative fees related to the towing, storage, and processing of the vehicles. These fees are usually higher than the parking fines for the violation.

Another tool used in parking enforcement—particularly to deal with habitual parking offenders and nonpayment of citations—is the use of wheel clamps. Also known as “parking boots,” these metal devices are designed to clamp onto a vehicle's wheel to prevent the driver from moving the vehicle or from removing the wheel itself. Drivers must pay their parking tickets before the enforcement agency will unlock the wheel clamp. The use of the boot is also a way to reduce cost, because personnel no longer need to wait for tow truck drivers.

Compliance

The parking enforcement field is typically rife with conflict. Occasionally, enforcement personnel encounter drivers when issuing a citation. How these personnel interact with drivers depends on the context, but these interactions are usually stressful for both parties. Parking enforcement personnel are subjected to verbal abuse and, occasionally, even physical threats, which can potentially impact their physical and psychological well-being. This can increase employee turnover and harm job performance, while lowering the probability of the public receiving tickets.

Although a perfect compliance rate is not expected, setting compliance goals can allow decision makers to determine whether their enforcement strategies are working as intended. The rate of compliance for a given regulation can be measured by conducting surveys of parking behavior, including the percentage of cars parked illegally. Technological interventions, such as in-pavement sensors, can determine in real time whether drivers have parked their vehicles too long or without having paid.

Information obtained from such technology can be relayed to parking enforcement officers, who can use it to seek out vehicles in violation and issue them parking citations. By increasing the probability that personnel will find cars violating parking rules, such technology could help keep parking enforcement costs from becoming too great a financial burden for public agencies.

Levels of Enforcement

Public officials have varying perspectives on an acceptable level of enforcement, based on public opinion as well as their personal judgment. Public pressure from merchants, residents, drivers, and the media can influence how parking enforcement tools are used. Setting parking fines is particularly controversial for paid parking because the public often believes that parking should be free.

The public has used equity arguments to limit parking enforcement—particularly for the level of fines. For example, a rich or poor driver pays the same amount regardless of the circumstance, which means that a fine will have a disproportionately severe effect on lower-income drivers and potentially no impact on wealthier drivers. Under public pressure and calls for fairness, elected officials have frequently avoided raising parking fines to levels that will improve compliance.

There are ways that public officials can reduce conflict and improve equity in the field of parking enforcement. With respect to paid parking, officials can allow drivers to pay for more time than they plan to use and receive a refund if they vacate their space early. This reduces the likelihood drivers will underestimate their stay and achieves paid parking's primary goal: creating turnover. It also reduces drivers' anxiety about paying for parking when they may not know in advance how much time they will need and their destination is too far away to refill the meter.

A police car parks near a solar-powered pay-and-display parking meter in Houston, Texas. Vehicle-mounted camera systems, license plate recognition, and handheld electronic parking ticket printers are among the new technologies in parking enforcement.

Another way to increase compliance without being heavy-handed is through the introduction of graduated parking fines. Under this system, the first ticket carries a relatively low fine, but the monetary fine increases with each subsequent ticket. This approach treats those drivers who regularly violate parking laws more harshly than the driver who might occasionally do so. To positively influence the politics of parking enforcement, an agency could, for example, dedicate some of the parking-fine revenue to the neighborhood in which the driver received a ticket. This mechanism likely increases support for parking enforcement.

Such funds could be used to pay for public services or improvements, much like parking meter revenue in a parking-benefit district. Legally, the fine also becomes a remedy for an infraction committed by the driver, which tends to have local effects either on parking supply or on safety. Moreover, dedicating

some of the revenue can reduce conflict between enforcement personnel and drivers. Some of drivers may feel less bitter if they know their fine will be used to improve an area and their future experience there.

Parking enforcement is intended to change driver behavior, manage parking as a resource, and raise revenues for municipalities. Technology can improve the compliance of drivers, but policies can also do so. Ultimately, though, parking enforcement depends on policies adopted by decision makers and which the public supports.

Parking Revenue and Collection

Most automobile parking is free to the motorist, yet is never free to the supplier. Many smaller cities and suburban areas have explicit or implicit policies to keep parking free to the user, but in central districts of larger cities and other locations with high

demand, parking pricing is common. Parking pricing is important, both as a demand management measure and, secondarily, as a source of revenue to offset costs incurred by parking providers.

In the case of publicly provided parking, that revenue can be used for enhancing both parking facilities and the destinations that draw motorists in the first place. Many parking fee-collection systems have been developed since the advent of the automobile, and these systems are evolving at a rapid rate.

Attended Parking

Attended parking represents the earliest form of paid parking. A human attendant serves as both cashier and enforcement agent, ensuring that all motorists parking in a controlled-access lot or garage pay an appropriate amount. In larger facilities, the attendants are posted only at the exits; automatic gates at entrances require entering motorists to take a time-stamped ticket, which must be presented with payment to the attendant before exiting the facility.

Some newer facilities have eliminated human attendants by using magnetic strip tickets to record time entered; before returning to their car, drivers must pay for their time at a machine that validates the ticket. Drivers are then given a grace period of several minutes so that they can return to their cars, drive to the exit, and insert the card that will open an automated exit gate.

Valet parking is a special case of attended parking. In this case, attendants park the vehicle for the motorist and then retrieve it when the motorist is ready to depart. This arrangement has advantages for both motorists, who can leave their car at the main entrance of an establishment, and for the establishment, which can utilize relatively remote parking, rather than needing to provide all parking on or near the site. Attendants are also able to park cars in a more space-efficient manner than individual drivers, so less total parking space may be needed. Operating costs of valet parking are higher than other forms of attended parking, though, because both the number and skill level of the attendants are higher.

Parking Meters and Pay and Display

The parking meter debuted in 1935 in Oklahoma City, Oklahoma. A coin-activated timer adjacent to an on-street parking space indicated to enforcement agents that an appropriate payment had been made, and time limits on the meter ensured

turnover of parking spaces. Parking meters soon became a common sight in major cities, and they remain the most common payment technology for on-street parking.

“Pay-and-display” multispace parking meters first appeared in the 1950s. Early coin-operated machines provided the customer with a receipt that was displayed on the customer’s dashboard. Because one pay-and-display machine can serve several on-street parking spaces, the capital investment and maintenance costs are potentially reduced for the local authority, although individual pay-and-display meters are more costly than single-space meters.

Another advantage of pay-and-display systems is that they prevent drivers from taking advantage of parking meters that have time remaining, since the proof of payment stays in the paying driver’s vehicle. More recent machines also accept multiple forms of payment—coins, currency, credit cards, and smart-cards—and some are able to provide change.

There are also off-street applications of pay-and-display. Major institutions (for example, universities and hospitals) often deploy pay-and-display systems. Visitors typically purchase time and receive a receipt from a machine to display in their cars, eliminating the need for an attendant at either entry or exit. Frequent parkers (for example, employees) can be allowed to purchase a long-term-parking tag or sticker, which is displayed on the vehicle itself and enables those users to avoid stopping to check in or out on a daily basis. Given these features, pay-and-display systems are much more efficient for both the customer (in terms of time) and the operator (in terms of labor costs).

Newer pay-and-display machines provide operators with remote access to their machines via wireless communication, enabling real-time monitoring for failure of the machines or tampering. They also enable credit-card authorizations and other forms of electronic payment in real-time, and, perhaps most importantly, they monitor parking demand on an ongoing basis and can reconfigure the rates and customer interface display remotely.

Emerging Payment Technology

A number of cities have implemented in-vehicle payment-and-metering devices that provide the motorist convenience of paying for parking through stored-value technology. The driver starts the meter (typically displayed on the car’s dashboard) upon

parking, and the device deducts from preloaded amount of money digitally coded into the device. If parking rates vary by district, the motorist may need to indicate the parking rate, as well as the start and end times. Value can be replenished electronically. In addition to being more convenient for users, in-vehicle payment systems have the added benefit that the driver is charged only for the actual time spent.

In the larger economy, new technologies have dramatically changed the way small payments are made in retail and service establishments. Key among these new technologies are contactless smart cards (CSCs) and mobile phones enabled with near field communication (NFC) technology. These smart cards and NFC phones have been increasingly used for transit-fare collection since the 1990s, and they are playing an increasing role in parking-fee payment and collection.

Fee calculations are performed with bar code and magnetic-ticket processing, thereby eliminating paper tickets and currency handling, and reducing field service and maintenance costs for parking meters and other payment machines. Moreover, wireless electronic access control systems do not require on-site power or network communications, although still providing real-time data about parking usage.

Pay-by-phone is becoming more common as smartphone applications for secure payments become ubiquitous. By replacing much of the technology surrounding paying for parking with users’ cell phones, substantial capital and operational savings are possible. In addition, parking rates can be adjusted quickly, enabling parking operators to adjust parking rates to match fluctuating demand.

Many emerging payment technologies have been brought together by the City and County of San Francisco in an advanced parking management system known as SFpark, launched in 2011. The SFpark system uses sensors, smart meters, and demand-responsive pricing to collect and distribute real-time information about where parking is available, enabling motorists to more quickly find open spaces. To help achieve a desired parking availability of 15 percent by zone or block, SFpark periodically adjusts meter and garage pricing up or down to match demand. As of May 2013, there had been 10 such pricing adjustments. Rates can vary by block, time of day, and day of week.

Demand-responsive pricing encourages drivers to park in underused areas and garages, reducing demand in overused areas. Motorists may pay by cash or electronically, including by cell phone. The overall aim is to use real-time data and demand-responsive pricing together to readjust parking patterns so that parking with a location and price acceptable to a given motorist is easier to find.

Parking Structures

The multistory parking garage or car park is a fundamental element used in urban and transportation planning in many countries in the world because it provides a relatively compact way to store a large number of automobiles. Although most modern parking garages use straightforward, rectangular designs, they differ in major ways from most buildings because of the weight of the automobiles they house and the fact that those automobiles will be moving through the structure. From a design perspective, open parking structures must be designed to allow efficient snow removal and drainage, and closed structures must adhere to strict specifications regarding ventilation.

Parking structures are seldom constructed in a vacuum, and so they can have major impacts on the areas in which they are located, affecting vehicle and pedestrian traffic, security, and aesthetics. Therefore, the size, location, and appearance of

parking structures should be planned as part of an overall urban or suburban design.

History

Although a few parking mass garages were built early in the 20th century, elevated parking structures did not start to become common until the 1920s, when the number of automobile owners had increased substantially, and more people were using their cars for transportation into urban areas. The familiar rectangular, multistory concrete structure with ramps providing access was well-established by the end of that decade, and some structures were quite large. For instance, the Autorimessa in Venice, Italy, designed by Eugenio Miozzi, had spaces for 2,500 cars.

One difference between these early parking garages and those designed today is that the early structures were usually enclosed, like warehouses, and often embellished with elaborate exterior decoration. Although some were notable in aesthetic terms, they had limited ventilation, allowing for the dangerous buildup of carbon monoxide within the garage.

In the 1950s, different patterns of parking structure location evolved in Europe and the United States. In European cities, many of which had been devastated by World War II bombs, a typical model included a pedestrian zone in the central downtown area, with multistory automobile garages built around the perimeter. In 1963, the English civil engineer Colin Buchanan predicted that the car park would become an expected part of destinations, including workplaces and shopping areas.

In the United States, rapid suburbanization and the growth of shopping malls also made planning for parking an important consideration in new construction. In fact, the term *parking center* was once proposed for what is now called a shopping center, because it was assumed that the adequate parking provided would be part of the attraction of shopping there.

Richard Neutra suggested the construction of open-air car parks in 1940, but the first to open for business was in 1948 in Miami, a Bauhaus-inspired, split-level structure designed by Robert Law Weed. Without the ventilation concerns of previous car parks, as well as lower construction costs, the open-air model soon became the norm for new car parks.

A later innovation was the development of mechanical garages, such as Speed-Park in New York City. Built in 1961, it provided fully automated parking and retrieval for 270 cars using a system of elevators. Although an automated system could fit more cars into the same amount of space, construction and maintenance costs tend to be higher, and this design is far less common than garages with ramps that allow drivers to get to and from their parking places. Another innovation was the integration of parking into urban residential buildings, such as Chicago's Marina City, a downtown apartment complex constructed in 1962.

Planning and Policy

Author Todd Litman has found that the typical car is parked an average of 23 hours per day and uses several parking spaces per week. To accommodate these mostly motionless vehicles, parking facilities now constitute a major type of land use. The question in most parts of the world is not whether to plan and design for automobile parking, but how to do the best job for a given circumstance.

The location of parking spaces can be as important as the number of spaces available in terms of resident or patron satisfaction, and different strategies can be used to increase parking efficiency and/or reduce parking demand.

Planning for parking, including the location of car parks, how large they should be, and the amount to be charged (if any) for their use, should be part of an integrated environmental design. For instance, shoppers often overlook the availability of open-air garage spaces because they are less immediately visible than on-street parking. However, many would use the garage space if adequate signage directed them there.

Placement of garages near the fringe of an urban area, with provision of mass transit into the city center if the distances are great, can be more economical than providing parking within the central business district. Such location of parking structures can also reduce traffic congestion and air pollution in the city. However, drivers may need to be educated about their options, and pricing strategies can also be used to encourage them to use peripheral garages rather than driving directly to their destination.

The Victoria Transport Institute (in Victoria, British Columbia, Canada) offers a table of

This open-air parking structure is built into the residential towers of Chicago's Marina City, a downtown apartment complex constructed in 1962. The complex inspired later parking structures built into large developments in the United States.

hypothetical cost recovery prices for different types of facilities, using estimated costs for land, construction, and ongoing operation and management. For instance, for a four-level structure in a central business district, the monthly rate for cost recovery alone would be \$150, versus \$135 for an urban three-level structure, \$75 for an urban surface lot, \$115 for a suburban two-level structure, and \$35 for a surface lot built on free land.

Of course, other factors may also be used to set prices. When demand for parking outstrips supply, as in many large cities, fees can be set at a high rate and the parking structures will still be relatively full. Higher-than-recovery pricing can also be used to shape behavior. For example, the Victoria Transport Institute cites a 1993 study showing that relatively

small increases in parking fees could result in substantial reduction in the number of vehicle trips to a location, particularly if alternative means of transportation are available.

Finally, aesthetics and environmental impact should also be considered. A compact parking structure may be more appealing than a large expanse of paved lots, and it allows more of the land area to be reserved for parks or other purposes.

Design

The design of a parking structure should be based on the requirements of the expected users. Will they use the facility every day, as in employee or resident parking, or will many users be infrequent guests of the facility, as in shopping mall parking? In the latter case, good wayfinding aids (signage, visibility) will be necessary, while in the former case, they will be less important. If the users are short-term parkers, for example, they may be more interested in the ease of finding a space and exiting quickly, and so planners may reserve some of the most convenient spaces for visitors (often charging a higher fee for those spaces) while reserving more distant spaces for residents or employees.

Another consideration is whether to allow for one-way or two-way traffic flow through the facility. One-way traffic makes it easier for drivers to get in and out of parking spaces, and requires less space be devoted to the driving aisles, while two-way traffic offers better visibility, safer pedestrian access, and a more natural pattern of driving—as well as eliminating the possibility of a driver accidentally turning the wrong way into one-way traffic.

Structures designed for one-way traffic generally have angled spaces, while those with two-way traffic generally have spaces perpendicular to the aisle. Normally, angled spaces are arranged to point toward the exit. New buildings in many countries are required to include a number of spaces for people with disabilities, and these must also be integrated into the structure design.

Particulate Matter

Particulate matter (PM) consists of a complex combination of organic and inorganic substances in the form of extremely small particles and liquid droplets, including uncombusted fuel, acids (such as nitrates and sulfates), dust, and metal fragments, and represents a hazardous by-product of the combustion process. Particulate matter also varies in size, ranging from some particles that can be seen with the naked eye, such as dust and smoke, to particles so tiny that they can be identified only with an electronic microscope.

Particle size is an important factor because it is directly linked to PM's potential for causing health problems. Particles with a diameter smaller than 10 micrometers can have the most serious health effects because they can pass through the throat and nose and enter the lungs. The U.S. Environmental Protection Agency (EPA) classifies PM into two families, according to size: "inhalable coarse particles" and "fine particles."

The “inhalable coarse particles” group includes PM with a diameter that ranges between 10 micrometers (μm) and $2.5\ \mu\text{m}$ and is generally referred to as PM₁₀. The “fine particles” group includes PM with a diameter smaller than $2.5\ \mu\text{m}$ and is designated PM_{2.5}. In comparison, a human hair is on average $70\ \mu\text{m}$ in diameter, making it seven times larger than the largest PM₁₀ particle and 30 times larger than the largest PM_{2.5} particle.

These particles, as mentioned above, can also be made of a wide range of chemicals. The composition is determined by their origin, which brings about a further classification of particles: primary and secondary particles. Primary PM is emitted directly from a source, such as fires, fossil fuel burning, construction sites, etc., or is formed by abrasion. The particles’ composition depends on their source; for example, particles originated by the interaction between the wind and rocks or the ground tend to consist of mineral oxides, while particles originated from sea spray are made of mostly magnesium, sulfate, organic compounds, calcium, or potassium, depending on the seawater composition.

Secondary PM is the result of the oxidation of primary gases in the atmosphere, which converts them from a gaseous phase to a subsequent condensed phase. Examples include nitrogen oxides and sulfur dioxides emitted from vehicles or power plants. Secondary particles may have an anthropogenic origin and form from gases derived by the combustion of fossil fuel or biomass burning, or a natural origin, such as from the photo-oxidation of natural volatile organic compounds (VOCs).

Other important constituents of primary and secondary particles can also be organic matter (OM) originated from anthropogenic (human-made) or biogenic sources, and elemental carbon (also known as “black carbon”). The secondary fraction of these two aerosols is a result of combustion products of internal combustion engines and has proven adverse effects on human health.

Sources

PM can be characterized by dividing it into the following categories by source. Particulates from vehicle exhaust emissions include particulate matter that is generated by vehicles, and this can be subdivided into two categories, primary emissions and secondary emissions. Primary particulate emissions are a direct result of the inefficient vehicular

combustion process; a small fraction of particulate deposits on the surfaces of the exhaust system, and it is then incorporated in the exhaust gases and emitted into the external environment. Primary PM emission rates generally decrease with increasing vehicle speed, when fuel combustion becomes more efficient, and are greater for diesel-fueled vehicles. Secondary particulates are formed in the immediate atmosphere from the condensation of exhaust vapors or by atmospheric chemical reactions.

Particulates from vehicular nonexhaust sources include a wide range of sources, which are mostly associated with turbulence/resuspension generated by vehicles, and the deterioration of vehicle components. The largest portion of PM originates from these activities. Their resuspension is dependent on weather conditions, such as precipitation, and therefore has a seasonal component, with peaks during dry months. Studies carried out by various researchers demonstrated that vehicle-induced turbulence is a contributory factor in the resuspension of particulate matter. This fraction of PM is mainly linked to road surface material, such as the wear of tires during braking and skidding, or the deterioration of brake linings during braking and road abrasion. The generation of coarse particulate from these sources increases with the vehicle speed.

A smaller fraction of particulate originates from other anthropogenic sources, such as domestic heating and industrial processes, as well as larger amounts generated by construction activities and mining.

Primary marine aerosol (sea salt) is among the largest contributors to coarse particulates originating from natural sources in coastal sites. This would also indicate wind speed as the main weather variable responsible for higher concentrations of coarse particulate from sea salt; higher wind speeds may result in higher concentrations.

Health Effects

Particulate matter has detrimental effects on human health and the environment, which vary according to size and composition of the particulates. With regard to adverse effects on human health, these are difficult to quantify because the wide range of sources of PM, both natural and anthropogenic, makes the nature of particulate matter highly varied. The health effects of PM depend on a wide

range of factors, which can be broadly grouped under the following headings:

Composition. Fine particles may belong to primary or secondary particulates, and they are comprised substantially of sulfates and nitrates, generally in the form of ammonium salts, together with organic and elemental carbon and a range of trace metals. These particles, along with the chemicals transported on their surfaces, can be highly acidic and potentially a source of lung inflammation upon inhalation.

Particle size. This is a key factor that determines exposure and human dosage. G. Oberdörster observed that particle surface area and dosimetry parameters, such as deposition, clearance, retention, and translocation and dissolution of inhaled particles in and to different lung compartments, were important for the persistence of particles in the lung and correlated with adverse pulmonary effects. He also completed a series of epidemiological studies, which have shown that ultrafine particles are causally involved in adverse responses seen in sensitive humans, such as the elderly with preexisting respiratory and cardiovascular diseases.

Epidemiological studies have shown a correlation between environmental particulate air pollution (PM₁₀) and a range of endpoints of lung morbidity and mortality, and an ultrafine fraction of the PM₁₀ particles is considered to be the principal mediator of these effects. Researchers have observed that with normal nasal breathing, larger particles of aerodynamic diameter between 10 and 100 μ m tended to be deposited in the extrathoracic part of the respiratory tract; particles in the range 5 to 10 μ m were deposited in the proximity of the fine airways; and fine particles (less than 2.5 μ m) tended to be deposited in the distal lung airway and airspace.

Length of exposure and dosage: a noticeable increase in lung cancer mortality has been found with even a small increase in particulate air pollution, and positively associated exposure to fine particulates with death from lung cancer and cardiopulmonary disease. A connection has been found between acute respiratory effects and exposure to PM.

A positive connection between long-term exposure to PM and lung cancer, as well as

cardiopulmonary mortality, has been proven. Chronic rat inhalation studies have shown that a number of different particle types can induce significant adverse effects, including impaired lung clearance, chronic pulmonary inflammation, pulmonary fibrosis, and lung tumors.

Exposure to particulate matter has been linked to acute reactions, such as irritative bronchitis (or industrial or environmental bronchitis), and chronic reactions, such as chronic bronchitis and pulmonary emphysema. Several studies carried out in different parts of the world resulted in a clear correlation between exposure to PM and increased respiratory, cardiovascular, and lung cancer mortality rates.

Environmental Effects

Effects on the environment can be broadly grouped under ecosystem damage, urban environment damage, acid rains, and visibility impairment. The deposition of the fine fraction of particulates has detrimental effects on the environment because of the high percentage of sulfates in this pollutant. Fine particulates can travel long distances with the wind, and primary and secondary particles that originated in an urban environment can impact distant ecosystems by settling on ground, vegetation, or water. This phenomenon could result in an increased acidity of surficial aquifers (lakes and streams) and into a variation of the nutrient balance in coastal waters and large river basins.

The deposition of fine particulates can also have an impact on sensitive forests and farm crops; mineral acidic dust may directly damage leaf tissues by corroding them, or indirectly have an adverse effect on plants by altering the soil pH and depleting the nutrients in the ground. The dust on the leaves can also affect the energy exchange between vegetation and the atmosphere by reducing the amount of light available for photosynthesis. As such, agricultural and natural ecosystems may experience reduced productivity or a disruption of nutrient cycles, which may result in the decimation of sensitive animal and vegetable species.

In urban environment damage, the high percentages of sulfur dioxide (SO₂) and nitrogen dioxide (NO₂) in the chemical composition of fine particles have a great impact on construction materials and paints. As it was reported by the National Research Council in 1979, primary and secondary "acidified"

particles may have a devastating effect on the surfaces of buildings and monuments, causing damage and soiling and decreasing the aesthetic appeal of such structures. PM aggravates the degradation of structures that typically arises from long-term exposure to natural agents, such as wind, sun, temperature, and humidity fluctuations. Acid-forming aerosols have been reported to damage various building stones and cement products, and to cause discolorations, and loss of gloss and thickness of the paint film layer, both of which may have serious economic consequences.

With acid rains, SO_2 and NO_x (nitrogen oxides) are among the pollutants that can react with water in clouds to form acid rain. SO_2 can react with water vapor and sunlight to form sulfuric acid, while some of the nitrogen can react with water to form nitric acid. These reactions are slow to complete, and they may take place while the polluted mass of air is pushed by wind to locations that may be hundreds of miles away from the pollution sources. As such, acidified primary and secondary particles originated in an urban environment can impact distant ecosystems, causing acidification of lakes and streams and damaging sensitive forest trees and soils.

Acid rain is also very harmful to the life in the water, polluting surface water and then causing the death of sensitive aquatic fauna. In urban environments, acid rain contributes to the decay of building materials, sculptures, and paints. Even mist and fog can be acid; pollutants may be removed from the air in the form of condensed droplets saturated with chemicals such as sulfur dioxide and nitrogen oxide, which can turn out to be more strongly acid than acid rain.

Primary and secondary acidic aerosols may contribute to visibility impairment before they condense into acid rain or acid fog droplets. In urbanized areas, high levels of fine particles may result in reduced visibility in the form of haze. Under conditions of high humidity, the interaction of the solar radiation with polluted air results in a reduced clarity and affected color of the sky. These two visibility outcomes may vary according to the chemical composition of the aerosol, because different components differently modify the overall refractive index and thus affect how much light is scattered and absorbed. For example, the presence of PM containing sulfate, a derivative of SO_2 under

high-humidity and low-temperature conditions, may result in a yellow haze.

Smog is another by-product of high concentration levels of primary and secondary PM constituted of mineral dust, carbon monoxide and elemental carbon, sulfur dioxide, nitrogen oxides, and organic matter. High concentration levels of either organic matter or black carbon may form into a strongly light-absorbing aerosol that affects the atmospheric radiation field by both scattering and absorption.

Partnership for a New Generation of Vehicles

The Partnership for a New Generation of Vehicles (PNGV) was a joint venture between the U.S. government and the U.S. Council for Automotive Research (USCAR), a collaborative research initiative established by the "Big Three" U.S. automakers: DaimlerChrysler Corporation, Ford Motor Company, and General Motors Corporation. Also known as the Clean Car Initiative, the partnership sought to develop technologies for fuel-efficient, low-emissions vehicles that are safe, affordable, and appealing to the broad consumer market. While the program achieved the majority of its mandate, it fell

short of its final goal of delivering a concept car prototype for production.

In addition to its tangible outcomes related to automotive technologies, the partnership also served as an important early experiment in government–industry collaboration. PNGV’s experiences helped pave the way for future cooperative efforts between federal agencies and U.S. commercial interests in the automotive arena, as well as in other industry sectors.

Formation of the Partnership

USCAR was formed in 1992 in response to increasing globalization in the automotive market, which had resulted in a surge of new competition for U.S. automakers from their counterparts in Europe and Japan. With congressional passage in 1984 of the Cooperative Research Act, which limits the anti-trust liability of joint research and development ventures, the U.S. automakers recognized an opportunity to work together within a technical collaboration to bolster their global positioning.

They created the Automotive Composites Consortium in 1988 to address a need for new structural and semi-structural polymer composites, and soon began working to resolve other issues that involved technologies, such as advanced batteries and vehicle recycling. Four years later, USCAR was formed as a management group to coordinate all the joint research and development efforts among the three automakers.

The Bill Clinton administration brought the federal government into the mix on September 29, 1993, when it established the PNGV as an industry–government partnership under the U.S. Department of Energy (DOE). It was dedicated to amplifying U.S. automotive competitiveness through the collaborative development of technologies that would create a new generation of vehicles featuring significantly enhanced fuel efficiency and reduced carbon dioxide emissions.

The partnership combined the vast research and development resources of the DOE’s National Laboratories and various academic research institutions with the automobile design, production, and marketing capabilities of USCAR and its partners and suppliers. Generally, the U.S. government funded development of long-term, high-risk technologies under PNGV, while USCAR and industry constituents typically funded development of technologies that had nearer-term commercial potential, as well

as provided funds for the adaptation of government technologies to automotive applications and the production of proof-of-concept vehicles.

At PNGV’s request in 1994, the National Research Council created the Standing Committee to Review the Research Program of the Partnership for a New Generation of Vehicles. The committee conducted annual reviews of PNGV’s research programs, reported on the partnership’s progress to government and industry, and identified potential barriers to PNGV’s success.

Internally, PNGV created several technical teams responsible for specific areas of research and development, such as subsystems, manufacturing, electrical and electronics power-conversion devices, materials and structures, and systems analysis.

Objectives of the Program

PNGV’s key goals were threefold. First, the joint venture sought to appreciably improve productivity and U.S. competitiveness in automotive manufacturing for future generations of vehicles. Toward that end, the partnership targeted research designed to upgrade U.S. manufacturing technology, improve production speed and flexibility, reduce manufacturing costs, decrease environmental impact, and advance overall quality. Second, PNGV targeted implementation of commercially viable innovations to vehicles that could generate better fuel efficiency and fewer emissions than conventional vehicle designs, while maintaining or improving vehicle safety performance.

Research in support of this goal was focused on technologies that reduce the energy requirements of the vehicle’s engine and drivetrain, which is comprised of the parts of an automobile that connect the transmission with the driving axles. The third key goal of the PNGV involved the development of vehicles that could achieve up to three times the fuel efficiency of comparable conventional models while maintaining relatively equivalent cost of ownership.

A steep rise in international oil prices in 2000, matched by climbing gasoline prices in the United States, garnered media attention about the high cost of U.S. driving and the need for fuel economy. The attention strengthened PNGV’s position, but gas prices and fuel efficiency were not major issues that motivated most U.S. drivers at the time. In fact, the early 2000s were the boom years for less-fuel-efficient sport utility vehicles. There was little

enticement for consumers to purchase vehicles featuring higher-cost components and designs merely to improve fuel economy.

That is why it was critically important for PNGV to achieve its goal of developing an affordable vehicle with a fuel economy of up to 80 miles per gallon (mpg) that matched performance, size, utility, and cost of conventional models, while at the same time meeting stringent safety and emissions standards. It was believed that such a vehicle potentially would overcome the lack of economic incentives for consumers and encourage them to purchase a next-generation automobile with greater fuel economy. The contention was that if the partnership achieved its goal and delivered a cost- and attribute-equivalent vehicle, with the added feature of improved fuel efficiency, there would be no reason for buyers to favor conventional models.

The ambitious goal sparked rapid development of vehicle technologies designed to improve fuel economy, including higher-efficiency engines, hybrid drivetrains, and regenerative braking systems.

Achievements

The partnership made substantial progress in its first several years and achieved several significant milestones during that time. By the end of 1997, PNGV reached an important target and succeeded in making technology selections for alternative vehicles based on assessments of system configurations. The group chose the four-stroke compression-ignition direct-injection (CIDI) engine as the most likely option to achieve the stated fuel economy goal in the specified timeframe, although high-efficiency, fuel cell power plants were considered an extremely promising long-range technology option. Once PNGV selected the technology, the joint venture was able to focus its resources on fewer technologies, which would help it define and develop concept cars by 2000, with prototype production slated by 2004.

Employing technologies developed through PNGV in conjunction with their own proprietary technologies, the USCAR automakers each succeeded in developing separate concept vehicle designs by the 2000 target date that, in theory, would generate fuel economies ranging between 70 mpg and 80 mpg.

Chrysler created the ESX-3, Ford developed the Prodigy, and General Motors designed the Precept.

At about the same time, the U.S. Environmental Protection Agency (EPA) released significantly more stringent emission standards for particulate matter and nitrogen oxides compared to those required at the start of the PNGV program. The change called into question the ability of USCAR to meet the emission requirements with the selected CIDI engine in a prototype model by the 2004 deadline.

However, alternative engine options such as homogeneous spark-ignition engines or gasoline-fueled direct-injection engines, which had a better chance of meeting the new emissions standards within the PNGV timeframe, were not as fuel efficient as the CIDI engine. The PNGV participants tried to address the dilemma by reallocating a large portion of the program's resources to projects aimed at resolving the unexpected issues arising from the new federal standards. The efforts were unsuccessful in the end, and none of the Big Three introduced concept car prototypes by the initiative's 2004 deadline.

While the prototype goal was not met, the partnership did generate viable manufacturing and engineering innovations. One such innovation involved the development of a process to convert gasoline to hydrogen for fuel cells. Based on that technology, PNGV transitioned to become the FreedomCAR and Vehicle Technologies Program in 2002, with a new focus on hydrogen and fuel cell research.

Perspectives on the Program

DaimlerChrysler, Ford, and General Motors maintained a manageable, productive partnership with the DOE under the PNGV initiative. The program served as a role model for the approach of its successor, FreedomCAR, and a number of subsequent joint efforts between government and industry.

The core structure of the initiative involved maintaining a few key private partnerships to help reduce complexity. However, having a limited exclusive group of partners can lead to difficulties if there are conflicts of interest among the participants. In the case of PNGV and FreedomCAR, for example, the automakers could potentially be less likely to direct their collaborative research efforts and funding toward technologies that could require stricter standards, costlier production methods, or increased competition.

In terms of funding, the partnership arrangement was inequitable. Federal contributions to the

program ranged from \$100 million to \$200 million annually. In comparison, the combined contribution from the three automakers came to nearly \$1 billion each year. The enticement for the Big Three came in the form of unprecedented access to information, not only about evolving technologies, but also about each other and the inner workings of the government. The sharing spirit broke down toward the end of the partnership as each of the automakers became more guarded about their proprietary information as they neared the production stage for their individual concept vehicles. Outside of the PNGV, the program served to ignite industry interest and pursuit of new more efficient, environmentally friendly automotive technologies.

Passenger Van Safety

The Federal Motor Carrier Safety Administration, part of the U.S. Department of Transportation, defines a passenger van as a vehicle carrying 15 or fewer passengers with a varied storage capacity and no restroom facilities. Passenger vans are longer, higher, and wider than smaller passenger vehicles, and they require different driving techniques and strategies. Drivers must rely more heavily on side

mirrors for changing lanes, and they need more road space and additional braking distances. If they are not properly driven and maintained, passenger vans run a higher risk of crashes and rollovers, but if they are properly driven and maintained, the National Highway Traffic Safety Administration (NHTSA) statistics show that vans, defined as minivans and larger, have a lower overall death rate than other passenger vehicles.

Fifteen-passenger vans, originally designed as cargo vans, feature longer bodies and a higher center of gravity, and are less stable and more likely to roll over than smaller vans. Since these vans are used to transport sports teams, church groups, senior citizens, and large groups of people, rollovers and other types of accidents may produce multiple fatalities.

The backs of 15-passenger vans extend 4 to 5.5 feet beyond their rear wheels, so overloading causes instability during emergency situations like turning suddenly to avoid a pedestrian or a vehicle. Sudden turns cause the vans to fishtail, and since they are top and rear heavy, they are predisposed to rollover accidents.

Twelve-passenger vans appear not to have the same rollover problems, and NHTSA research has proven that the rollover risk of 12- and 15-passenger vans escalates significantly when the number of occupants increases from less than five to more than 10. In single-vehicle crashes, vans with 10 or more passengers experienced nearly three times the rollover rate of vans that were lightly loaded. NHTSA reports that inexperienced drivers, improperly sized and inflated tires, and incorrectly loaded cargo and passengers that alter the center of van gravity increase the risk of rollovers.

Fifteen-Passenger Vans

Fifteen-passenger vans are large vans with five rows of seats that are designed to carry up to 15 people, including the driver. They first appeared on the U.S. vehicle market in 1972 as a way for small groups of people to travel together instead of using buses. Many businesses including day care centers, churches, airports, and schools use them. The U.S. Army even bought 15-passenger vans as a matter of economy and convenience.

These 15-passenger vans quickly became popular, with annual registrations increasing from about 150,000 in 1990 to more than 500,000 in 2005. In July

2012, there were about 672,000 registered 15-passenger vans, making up about 0.2 percent of the total vehicle fleet in the United States. The Ford Econo Club E-350, made since 1978, is the most popular model, with 62 percent of registrations. The Ford E-350, the Chevrolet Express 3500, and GMC Savana 3500 are the three most popular passenger vans currently being manufactured in the United States.

Design Issues and Tire Problems

According to the NHTSA, 1,090 people were killed in 15-passenger vans in the United States from 1997 to 2006, with rollover accidents responsible for 63 percent of these fatalities. Many of the crashes involved a large number of passengers from schools, churches, and senior centers because these groups use the vans so widely. The 15-passenger van accidents were highly publicized and prompted research into the design of the vans. The NHTSA reports that the 15-passenger vans have multiple engineering problems, including frequent rollovers. A 15-passenger van has a higher center of gravity, which tends to make it top- and tail-heavy, especially when it carries 10 or more passengers.

A top- and tail-heavy 15-passenger van poses a greater risk for a rollover accident than a smaller vehicle. When a 15-passenger van is fully loaded, it handles differently than when it carries only a few passengers and a light cargo load. Added weight in the back of the van increases the risk of fishtailing and if the van fishtails and causes the driver to lose control and then overcorrect, a rollover accident may happen.

The 15-passenger vans also tend to have tire problems. A simple error like improperly inflated tires can lead to accidents in large vans, because rear tire pressure is different than front tire pressure. Drivers who neglect to check the tire type and pressure that the manufacturer recommends unwittingly create tire imbalances and conditions for a blowout. Underinflated rear tires can overheat, leading to tire failure.

The seating design for large vans, a 2-3-3-4 configuration for a 12-passenger van and a 2-3-3-3-4 scheme for a 15-passenger van, allowing a small passageway along the right side of the van for loading passengers, distributes the weight load more heavily on the left rear tire. If the left rear tire is underinflated, it will generate heat, possibly causing a blowout, a loss of control, and an accident.

Safety Versus Buses

Some organizations purchase 15-passenger vans believing that they are acquiring a cheaper version of a bus, but buses are designed with more safety features, including four rear tires. Van riders often assume they do not need seat belts or shoulder harnesses because most buses do not have them, but the NHTSA states that nearly 80 percent of 15-passenger van fatalities occur because passengers did not use their safety restraints.

Unlike 15-passenger vans, buses often have laminated glass windows and compartmentalized seating, but van passengers not belted in are likely to be thrown through shattered glass during a crash. Fifteen-passenger vans also do not have the interior padding that buses have to protect passengers from being slammed into rigid surfaces. Many buses also have first-aid kits and emergency exits, which save lives in crashes. Buses also have reinforced sides that keep the roof from collapsing in a rollover crash, but when 15-passenger vans roll over, the roof usually collapses all the way to the seats.

Twelve-Passenger Vans

Twelve-passenger vans do not appear to have the same issues as 15-passenger vans, and the NHTSA has issued safety warnings only for 15-passenger vans. The Chevrolet Express/GMC Savana 3500, Ford E-350, and Mercedes Benz Sprinter 2500 are three current models of 12-passenger vans. The NHTSA gives the Express, Savana, and E-350 three stars out of five for rollover resistance and the Sprinter just one star. The experience and skill of the driver is the biggest safety variable. Drivers lacking experience and skill have been major contributors to 15-passenger van accidents.

Safety Advice

Testing has shown that adding dual wheels on either side of 15-passenger vans adds to the vehicle's stability and improves handling in turns and emergencies. A van manufacturer retrofit of the 500,000 vehicles on the highway is estimated to cost about \$300 to \$400 per vehicle or about \$135 in mass-producing new vehicles. In the long term, the vans need to be redesigned to protect passengers in rollover and side impact crashes.

Public Citizen, a nonprofit consumer rights organization based in Washington, D.C., researched, wrote, and published a study titled "Stopping

Rollovers: The Dual Wheel Solution,” asking Ford Motor Company and General Motors Corporation to redesign future 15-passenger vans to diminish rollover propensity, to improve crashworthiness, and to retrofit existing 15-passenger vans with dual rear wheels to reduce rollover susceptibility. Ford and General Motors have not recalled any 15-passenger vans for wheel retrofitting.

According to Public Citizen, the original manufacturer or its dealers should be the only places that refit the 15-passenger vans with dual rear wheels. Aftermarket shops might not realize the complexity and vehicle impact of a dual wheel retrofit and such work would probably require a waiver of their own liability before they would convert any vans. Public Citizen states that since the manufacturers are responsible for the safety hazards on the 15-passenger vans, they should fix the problem and it recommends pressuring the manufacturers to fix the vans. It advises drivers buying new vans not to purchase 15-passenger vans.

Safety Recommendations

The NHTSA and the National Transportation Safety Board state that the ideal solution to the 15-passenger van problem would be retiring and disposing of the van and using a small school bus or other, safer vehicle for transportation. If it is necessary to continue to use the 15-passenger van, these agencies offer some recommendations to lower the risk of rollover and other accidents in 15-passenger vans:

- Screen all drivers of 15-passenger vans. The best course of action is requiring van drivers to secure a commercial driver’s license.
- Remove the rear seat of the vans to reduce loading behind the rear axle.
- Limit the capacity to nine people, including the driver. This dramatically reduces the top-heaviness of the van and the risk of a rollover.
- Load forward seats first.
- Communicate with passengers, parents, and other parties about the high risks of 15-passenger vans.
- Do not tow anything behind the vehicle or load the roof.
- Conduct a full safety inspection of the vehicle, including all tires, before and after the trip. Check the manufacturer’s specifications for tire inflation.
- Include safety items on board, such as a fire extinguisher, first aid kit, and cellular phone for emergencies.
- Require all passengers and the driver to wear proper safety restraints any time the van is in motion.

Federal law prohibits selling or leasing new 12- and 15-passenger vans to transport high school and younger students because of the higher rollover risk. Some colleges, universities, and business organizations have instituted policies against using 12- and 15-passenger vans.

Pavement Management Systems

Integral to surface transportation is the quality and condition of the surface itself, that is, the pavement used for roadways. Pavement management is the sum of all combined and coordinated activities in design, construction, maintenance, rehabilitation, and resurfacing that are needed to keep road surfaces safe for the modes of transport for which they were installed. From long experience, and with an eye toward protecting this vast, public capital-intensive resource, various industry and government partners have worked together to create and refine a set of policies, functions, and metrics that together are known as pavement management systems. As defined by the American Association of State Highway and Transportation Officials (AASHTO), these systems comprise and facilitate directing all the planning and operational activities “involved in providing and sustaining pavements in a condition acceptable to the traveling public at the least life cycle cost.”

The Greenroads Foundation points to pavement management systems as one subset of asset management systems, which it defines as “a formal systematic process of maintaining, upgrading, and operating a particular asset or network of assets, such as pavements and bridges.” Greenroads also focuses on preservation, which it defines as “a set of maintenance and rehabilitation practices used to improve condition and extend life of a structure(s).”

MAP-21

Highways and roads, whether interstate, state, county, or local, are the critical circulation network of the automotive surface transportation mode. Recognizing this, the executive and legislative branches of the United States have long made focused efforts to promulgate consistent policy, allocate resources, and monitor standards to ensure that this strategic asset is well maintained.

The most recent of these focused efforts came in 2012. In its Moving Ahead for Progress in the 21st Century Act (MAP-21) framework, Congress made federal funds available—a minimum of \$12 million annually—through the Technology and Innovation Deployment Program to accelerate the implementation and deployment of pavement technology in

A team repaves Interstate Highway 84 in Oregon in 2013. The Federal Highway Administration has the authority to compel states to correct substandard pavement conditions, including on their portions of the interstate highway system.

the United States. MAP-21 also updated the power of the Federal Highway Administration (FHWA) to compel states to comply with necessary corrective actions when pavement conditions are substandard—including on their portions of the interstate highway system.

MAP-21 empowered the U.S. Department of Transportation (DOT) to work in conjunction with state DOTs, metropolitan planning organizations, and other stakeholders in the establishment and review of performance measures for pavement conditions. These metrics will vary by geographic region, based on climate, road usage, and other factors. States must document the work they are performing or have plans to remedy situations where pavement has fallen below the codified performance levels.

Survey, Analysis, and Decision

The various state highway planning, engineering, and construction administrators, too, generally

have a solid record of policing their own best practices. These practices, and the principles that underlie them, have been developed hand in hand with private industry in the form of construction companies, material and component manufacturers, and labor unions, and with scientists and academic researchers.

Among the principles that pavement management systems comprise, there is some general agreement on key components. These include (1) manual and digitally enhanced surveys of pavement condition, (2) capture and compiling of the survey statistics in searchable databases, (3) interpretive structured analysis of the data, (4) a set of criteria used for decision making with regard to findings, and (5) practical methods to implement the findings.

Professionals working with pavement management systems have assembled and integrated these principles into working models through the application of an evolving suite of software products that incorporate geographic information systems, relational database interface graphics, decision-making guidance steps, and other modes—all with the goal of making the information clear, readily accessible, and actionable in real-world scenarios.

The information gathered and the decisions that are generated are proposed and ultimately implemented in either a project-level approach or a network-level approach. Considered in another way, these are a choice between bottom-up and top-down. Sometimes at the network level, the finer-grain data with extremely accurate statistics on local conditions is glossed over so that executive decisions can be made system-wide. Such top-down decisions are made with macro-budget priorities in mind. Passing these decisions down the chain to the project level means that project managers must then determine how best to allocate the resources and directives they are given across their timeline and their list of project tasks and local resource availability.

This situational approach to pavement management likely cannot be avoided—and it certainly is not without its own inherent advantages. For one thing, project managers exert some influence on the top-level decisions, as they are responsible for much of the interpretation of project-level data, and they are often called upon to provide much of the context for those decisions. Similarly, due to project managers' familiarity with changing conditions over time in a given locality—road wear, seasonal

fluctuations in traffic composition and flow, etc.—they are typically able to offer expert advice with less available systematized data.

Local-level highway and transportation officials are also by functional position less concerned with macro-level political and economic pressures and influences, which can distract executives from making priority decisions based solely on hard science and hard-won experience. With greater investment in the practical methods and outcomes they know and trust, project-level managers have less reason to be concerned about pleasing outside influencers. They have to please the drivers who use their roads, and their own immediate supervisors. This simplifies their worldview when it comes to interpreting pavement management data and making pavement management decisions.

Practical Metrics

AASHTO, among other bodies, has emphasized the practical refinement of several essential metrics for the analysis of pavement condition by means of periodic surveys. Among the pavement conditions that routinely must be assessed are (1) surface distress, (2) structural capacity, (3) roughness, and (4) surface friction or skid resistance.

Surface distress is the most frequently utilized factor on the part of maintenance crews and supervisors in determining a schedule for and type of remedial action; this type of survey comprises the measurement of observable type, severity, and quantity of distress. Such data is often entered into and forms the basis of a pavement condition index (PCI), which is instrumental in computing rates of deterioration and provides practical timetables for future distress checks and remedial activities.

Structural capacity utilizes nondestructive deflection testing of the pavement as a routine matter to determine load-bearing capacity. This must always be plotted against any and all future or projected traffic increases. In addition, the data from deflection testing often may be augmented by data acquired from core sampling and core component analysis.

Roughness, or ride quality, is generally a function of surface distortion of a pavement segment. From it is derived either a present serviceability index (PSI) or an international roughness index (IRI) reading. These indices are pragmatic measures of what is more broadly considered a perceived, qualitative

metric—the comfort of the ride as experienced by the driving public. However, it can be somewhat reliably converted into a vehicle-operating-cost matrix, and it is an especially important metric on mid- to high-speed roadways.

Surface friction or skid resistance refers to the ability to provide friction—particularly in wet or icy weather—sufficient to reduce or avoid skid-related hazards. This condition metric is especially crucial where vehicular traffic tends to operate at high speeds. A substandard measure of surface friction often will suffice on its own to determine the need for remedial maintenance on a pavement.

Life Cycle and Cost-Benefit Analysis

As decision making proceeds, the practical application phase of pavement management systems takes hold. Here, engineers and policy makers must employ the life cycle view where it affects consideration of the cost-benefit analysis of various outcomes. A decision as simple as whether to repair or replace a segment of pavement can be fraught with unforeseen complications unless the network-level expectations for the materials and finished product are understood from the outset.

In general, pavement management systems are geared toward the lowering of life cycle costs. This result, however, can be reliably attained only by adhering to proper and prudent inspection schedules, performing adequate data analysis, and scheduling the optimal timing of preservation activity.

Applied too early in the life or duty cycle of a pavement surface, remedial efforts will deliver too little benefit to defray the costs involved. Applied too late, the same efforts can deliver sizable benefit—but at a cost magnified many times above the cost for the same effort applied at the correct time in the pavement's life cycle.

Life cycle and cost-benefit analysis algorithms are built into various software packages to complement and assist in the decision-making capacity of pavement management systems' databases. These tools have been included because the measures are so vital to the management mission.

Conclusion

Pavement management systems can help highway authorities and engineers to achieve great savings, as well as to protect the public infrastructure and maintain safety—as long as they are used with

sensitivity to local transportation priorities and in accordance with state and federal mandates. The software and analysis tools will continue to evolve, but it is the professional approach of the planners and administrators, and the combination of their skill sets and experience, that will keep pavement management systems progressing in step with modern surface transportation needs.

Pedestrian Malls and Skywalks

Bringing back pedestrians into downtowns is an important goal claimed to contribute to a more vibrant urban center. A good environment for pedestrians would be one where many activities

A skywalk extends from an office building in downtown Tulsa, Oklahoma, in 2008. There were 30 skywalk complexes across North America by 2013, with the largest in Calgary, Canada.

could occur simultaneously without conflict among users, including drivers, cyclists, and pedestrians.

Two of the most common strategies that cities employ to separate pedestrians from vehicles are (1) the development of outdoor pedestrian malls, and (2) pedestrian skywalks. While advancing a similar intent of minimizing the conflict between pedestrians and vehicles, these two strategies have been applied in different contexts. For example, pedestrian malls are typically outdoor, street-level interventions, while skywalks are enclosed and elevated infrastructure. Additionally, each strategy's implementation poses different sets of issues and challenges, as well as distinct benefits and advantages. This entry examines both approaches in terms of their design, accessibility issues, and economic impact and as a congestion mitigation measure.

Downtowns are places of diverse activities and are strengthened by the image of being spaces where people walk. They accommodate a rich mix of uses,

including residential neighborhoods close to offices and retail as well as parks and recreational facilities.

Many downtowns are walkable because they were developed before the car became the primary mode of transport, and newer downtown redevelopment plans are recapturing that feeling by making their cities more pedestrian friendly. In the 19th century, downtown areas allocated almost half of their rights-of-way as walking space. The advent of cars, however, dictated that part of the walkways be converted to vehicle use. Traffic lights were installed to minimize vehicular delay. Vehicles conquered the pedestrian environment, and transportation planners yielded to the demand for space for cars, compromising the convenience and safety of pedestrians.

More recently, due to increasing concern about the environment and greater awareness of the importance of pedestrian-friendly downtowns, "pedestrianization"—defined as the method of transforming areas exclusively for pedestrian use—was introduced. Pedestrianization, considered the most influential driver of the street redesign movement, has changed the public environment of many cities. Two prominent pedestrianization strategies include the pedestrian mall and pedestrian skywalks.

Pedestrian Malls

A pedestrian mall is a street, typically fronted by commercial and retail stores, closed off to all forms of motorized traffic and accessible only on foot. These streets are regenerated to include pedestrian-friendly designs such as new paving, trees, and street furniture (such as park benches and café tables), as well as other amenities that provide visual continuity and special character, and help create an image and a sense of place for the downtown.

The closing of streets to car traffic is said to have originated in western Europe. The aim was to mitigate the escalating problems brought about by urban growth, a denser urban fabric, and increasing car share. Pedestrianization of shopping streets started as early as 1923, just after World War I, when the city of Coventry, in the English midland, was undergoing a downtown redevelopment. But, it was not until the late 1960s that Europe experienced a mushrooming of pedestrian malls. This trend shifted to the United States, which was largely influenced by German models.

One of the pioneer pedestrian malls in the United States is the Kalamazoo Mall designed by Victor Gruen and Associates in 1959 as part of an overall downtown traffic management plan for Kalamazoo, Michigan. By 1970, over 200 pedestrian malls had been implemented in small- and medium-sized U.S. cities.

Pedestrian malls can be categorized as a full mall, semi-mall, or transit mall. A full mall is a street closed to vehicular access that prioritizes pedestrian mobility. It requires physical improvement of the street to make it more pedestrian friendly. In a semi-mall, pedestrian space is expanded, but there is still provision for traffic and parking on a limited basis. Transit malls do not allow private car and truck traffic along the street and, along with pedestrian access, give way to exclusive public transport use. Some of the best examples of transit malls are located in Portland, Oregon; Minneapolis, Minnesota; and Madison, Wisconsin. The experience in European cities has been relatively positive for a number of reasons. These include a higher concentration of residents and workers within the city center, a more diverse mix of economic uses, and better public transport and land use integration.

On the other hand, a number of U.S. cities have experienced a decline in economic activities when pedestrian streets were closed off to vehicular traffic. Those that have succeeded were located in areas with high captive pedestrian markets, including housing areas located downtown, as well as universities, hospitals, and varied amenities (for example, Cornell University in Ithaca, New York).

By 2005, there were fewer than 24 pedestrian malls in the United States because most full malls had been reopened to car traffic once again. Municipalities found that allowing cars was positive for the economy. For example, the opening of Michigan Street in South Bend, Indiana, brought about a 20 percent increase in retail sales, while the opening of Jefferson Street in Burlington, Iowa, has led to a significant decrease in vacancy rates.

Skywalk Systems

A skywalk system is a series of interconnected, elevated pedestrian walkways that link adjacent blocks and buildings while ensuring total separation between pedestrian and vehicle traffic. The elevated walkway joins together a series of bridges right above the street, and second-level corridors

accommodate retail and services, as well as common areas for the public. Generally implemented in cities with cold climates, such as St. Paul, Minnesota, and Calgary, Alberta, Canada, these walkways are climate controlled and appear to simulate the indoor suburban shopping mall experience.

The design of the skywalk system in Des Moines, Iowa, for example, incorporates approximately 36 climate-controlled, glass-enclosed bridges that link 20 downtown blocks. This skywalk system is considered to have developed in an ad hoc manner, but the experience is said to provide a good case study for cities seriously contemplating implementing such a system. Its development is claimed to have increased the variety and vitality of the downtown center, which other cities can learn from and emulate.

The typical reasons for putting in place a skywalk are twofold—to separate pedestrian and vehicular traffic, and to protect pedestrians from the freezing weather. It eventually became clear that skywalks also served as economic catalysts, attracting customers to businesses within the skywalk network. As the network expanded, new developments demanded to be linked to the skywalk system.

The first skywalk system was implemented in Minneapolis, Minnesota, in 1962, and the largest skywalk system in North America has been built in Calgary. However, once skywalks became known as a way to stimulate economic development, they sprang up in some areas with milder climates, including Charlotte, North Carolina; Cincinnati, Ohio; and Dallas and Fort Worth, Texas. The number of skywalk complexes had grown to 30 across North America by 2013.

Compared to car-free pedestrian malls, skywalk systems give separate but equal downtown access to pedestrians and vehicles. The vertical nature of the separation, where pedestrians navigate on the upper level while vehicle circulation is relegated to the street level, may make pedestrians feel safer and more secure as they move around from building to building. Pedestrian malls, because they are at grade, require pedestrians to negotiate heavy volumes of car traffic when they are entering and exiting the pedestrian-only space.

Challenges

As in any development, good design—not only for aesthetics, but also for function—plays an important role in the success, or lack thereof, of

pedestrian malls and skywalks. For example, an ultra-lush landscape design in a pedestrian mall can sometimes impede pedestrian mobility or block views of retail entrances and displays. Portions of skywalks could have lengthy runs of uninteresting, blank walls. Whether above-ground or at ground level, pedestrian areas, like roads, require maps and signs to help people find their way. In a relatively compact pedestrian mall, people may navigate using existing street signs and retail signage. On the other hand, those visual cues may be lacking in skywalks, and signage must be added to keep pedestrians from becoming disoriented.

In contrast to open-air pedestrian and transit malls, elevated skywalks may appear to be private spaces, or perhaps even dangerous, making pedestrians feel uncomfortable in accessing them, especially if some portions of the walkways are closed off during evenings, weekends, or holidays. Access also becomes an issue when there is a lack of proper signage. In the absence of an area map, pedestrians may be uncertain if the skywalks will lead them to their destination, deterring the use of the walkways.

While upper-level skywalks generally accommodate quick-stop, service-oriented businesses that provide for the needs of pedestrians on the go, pedestrian malls tend to hold small, locally owned retail stores and shops designed more for leisure activity. Because of this, both strategies seem to attract different pedestrian groups.

The implementation of skywalk systems is considered to have spurred economic development and successfully encouraged pedestrian activity in city centers, but critics claim they can negatively impact ground-level retail activity, because pedestrian traffic moves to the elevated skywalk.

The presence of pedestrians, who serve as a captive market, is the key determinant of the success of both pedestrian malls and elevated skywalks. Cities and downtowns that lack an adequate captive market to support activities within pedestrian malls or skywalks are sure to fail. However, new groups of people can be drawn into the area, which entails commitment on the part of the city and private businesses to provide special events and entertainment on an ongoing basis.

In short, pedestrian malls and skywalks must be introduced not as an isolated measure but as part of an overall improvement plan for a downtown, complemented by an effective transport management

scheme. Furthermore, its success will also be dependent on the full support of all involved agencies and regular consultation with various businesses and civic groups.

Pedestrian Safety

Pedestrian safety considers incidents, injuries, and fatalities that occur to people who are walking or using a wheelchair, cane, electric scooter, or other assistive device. According to the U.S. National Highway Traffic Safety Administration (NHTSA), 4,280 pedestrians were killed and 70,000 pedestrians were injured in traffic crashes in the United States in 2010. Pedestrian fatalities accounted for 13 percent of all U.S. traffic deaths, which was comparable to other Western countries. Among developing nations Brazil, China, and Mexico, the percentage was much higher, between 23 percent and 29 percent. In Kenya, however, where a much larger proportion of the population relies on walking to get around, sharing roads with cars, trucks, and the ubiquitous *matatu* (unregulated minibuses), the rate is much higher at 47 percent.

Worldwide, the World Health Organization (WHO) reports that pedestrians make up the following proportions of roadway fatalities:

- Australia (2010): 13 percent
- Germany (2010): 13 percent

- Canada (2009): 14 percent
- United Kingdom (2010): 22 percent
- Brazil (2009): 23 percent
- China (2010): 25 percent
- Mexico (2009): 29 percent
- Kenya (2010): 47 percent

Crash Characteristics

The 2010 NHTSA data show that 73 percent of U.S. pedestrian fatalities were in urban areas, 69 percent involved male victims, 30 percent were between 8 P.M. and midnight, 33 percent involved a pedestrian with a blood alcohol concentration (BAC) of 0.08 or higher, and 14 percent involved a driver with a BAC of 0.08 or higher. People older than age 75 had the highest rate of pedestrian fatalities, but people between the age of 10 and 24 had the highest rate of pedestrian injuries per capita. In general, pedestrian fatalities and injuries are more common in locations, at times of day, and among socioeconomic groups that have more pedestrian activity.

Roadway design is associated with pedestrian safety. Street segments without sidewalks tend to have more fatal pedestrian crashes than segments with sidewalks. Pedestrian crash risk is higher on roadways with faster vehicle speeds, higher motor vehicle volumes, more travel lanes, and longer crossing distances than on narrower, slower streets. Intersections with right-turn channelization islands and signalized intersections that allow “right-turn-on-red” are associated with more pedestrian crashes. Median islands can help mitigate pedestrian crash risk at midblock locations, uncontrolled crossings, and signalized intersections.

Midblock pedestrian crossings with a pedestrian signal, pedestrian hybrid beacon, or rectangular rapid flashing beacon have higher rates of motorists yielding to pedestrians than locations with other types of crossing treatments. In addition, high speed limits and vehicle speeds increase the risk of severe pedestrian injuries. A recent literature review estimated that the chance of the pedestrian being killed is only 5 percent when struck by a vehicle traveling at 25 miles per hour (mph), but the chance of death increases to 15 percent at 35 mph, 40 percent at 45 mph, and 80 percent at 55 mph. Pedestrian injuries tend to be more severe than injuries to automobile occupants.

“Safety in numbers” is the concept that an increase in the number of pedestrians using a roadway

segment, crossing an intersection, or walking in a neighborhood area reduces the risk of each individual pedestrian being injured in a crash, independent of all other changes to the local environment. The causal mechanism behind this concept has not been identified, but researchers have hypothesized that it may be due to drivers being more aware of pedestrians in an area with more pedestrians (leading to more cautious driving), larger numbers of pedestrians reinforcing safe pedestrian behaviors (leading to more careful pedestrian street crossings), pedestrians choosing to walk in locations where pedestrian risk is lower (no behavioral reason), or other reasons.

Safety Evaluation

Pedestrian safety is typically evaluated using police-reported traffic collisions, or crashes. Police crash databases include only crashes that are documented in police reports. Minor pedestrian collisions with motor vehicles, pedestrian crashes in parking lots and on other private property, pedestrian falls, pedestrian collisions with fixed objects, or other pedestrian incidents are rarely captured by police crash reports.

Some of these additional pedestrian incidents can be captured in other sources, such as hospital emergency room records. Since pedestrian crash data are relatively sparse, surrogate measures of behaviors (for example, proportion of pedestrians walking in the roadway, proportion of pedestrians crossing against “Don’t Walk” signals, proportion of motorists speeding), and perceptions of pedestrian crash risk have also been used to evaluate pedestrian safety.

Spatial concentrations of multiple pedestrian incidents, injuries, and fatalities over a relatively short time period (for example, three to five years) are sometimes referred to as “hot spots.” These concentrations may indicate pedestrian safety problems. However, it is also important to recognize that pedestrian crashes tend to occur in locations with the highest pedestrian volumes. Therefore, the actual risk of a crash occurring to an individual pedestrian (expressed as the number of incidents divided by a measure of exposure) may actually be lower in some locations with many crashes than in other locations with few crashes. Example exposure measures include the number of pedestrian crossings at an intersection, pedestrian

crossing distance multiplied by pedestrian crossings, and pedestrian crossing volume multiplied by opposing-direction motor vehicle volume during a particular time period.

Safety Strategies

Common categories of pedestrian safety strategies include engineering, education, and enforcement. Engineering treatments are related to roadway and pedestrian-facility design. These treatments generally provide spatial separation between pedestrians and moving vehicles (for example, sidewalks, shoulders, and buffer space between the street and sidewalk), temporal separation between pedestrians and moving vehicles (for example, pedestrian crossing phases at a traffic signal), or slow-speed interactions between pedestrians and moving vehicles (for example, narrow roadways, raised median islands, chicanes, tight corner radii, curb extensions, raised crosswalks, and flashing beacons that alert drivers so that they can yield to pedestrians at a crosswalk). Roadway and crosswalk lighting enhance pedestrian visibility and safety at night.

Education treatments seek to improve the understanding of pedestrian safety laws and needs among all roadway users. Educational programs are typically offered through schools, state motor vehicle licensing departments, and law enforcement agencies. Safety messages can be shared in classrooms, through neighborhood walks, in print and broadcast media, online, and through social media. These messages are often tailored to specific audiences who have different physical abilities and levels of understanding (for example, elementary school students, college students, new immigrants, young drivers) and tend to target specific behaviors (for example, understanding and obeying pedestrian signals, wearing bright clothing at night, obeying speed limits, yielding to pedestrians at crosswalks).

Enforcement strategies are intended to reduce behaviors that decrease pedestrian safety and encourage behaviors that increase pedestrian safety. For example, targeted enforcement can target pedestrians crossing against traffic signals, drivers speeding, and drivers not yielding to pedestrians in crosswalks. Law enforcement is done by police, but neighborhood groups, parent-teacher organizations, and employers are often important partners in establishing strong enforcement activities. Law enforcement activities are

often combined with educational messages related to pedestrian safety.

Pedestrian Safety, Blind and Elderly

Pedestrian safety is affected by a range of factors related to road design and road-user behavior.

Pedestrians are often referred to as vulnerable road users, borne out by the fact that they comprise over 20 percent of those killed on the roads. There are specific dangers for pedestrians who are blind and/or elderly that are linked to specific behavioral characteristics and design features. These dangers do not always translate directly into heightened risk, detectable in accident statistics, as blind and elderly people often self-regulate their behavior in order to avoid these dangers and mitigate the risk. However, this tends to mean that they suppress their pedestrian activity, and so safety becomes closely linked with issues of access, inclusion, physical activity, well-being, and public health.

Blind and Elderly Pedestrians

The World Health Organization (WHO) estimates that there are 285 million people with a visual impairment throughout the world (approximately 4 percent of the global population). A great deal of diversity exists across this group, in terms of the severity of visual impairment (for example, 39 million are totally blind, approximately 0.5 percent of the global population), and in terms of the impact their impairment has on their daily activities. Visual impairment is known to be strongly associated with aging. For example, approximately 65 percent of visually impaired people are over the age of 65, and among those over age 50 the prevalence of visual impairment is thought to be between 10 and 20 percent.

Statistics on pedestrian accident risk specifically relating to blind and elderly people are not widely collected. Where statistics disaggregated by age group do exist, the picture is different in different countries. However, it is interesting to note that in the United States, the age group with the highest risk of being killed as a pedestrian was that over 75 years of age.

One of the key ways in which visual impairment impacts people is the way it affects them getting about as a pedestrian. In the largest recent survey of visually impaired people, “mobility on foot” was by far the most frequently reported travel difficulty among respondents. Particular problems cited by respondents to this survey included a lack of confidence in going out alone or to unfamiliar places, obstacles in the environment that made navigation more difficult, and fears about busy traffic. More generally, it is widely acknowledged that reduced walking speed

and slower reaction time among elderly people are particular risk factors, while the likely severity of an accident involving an elderly pedestrian will be increased due to age-related physical frailty. Consequently, for many visually impaired and elderly people, fear of getting around means they do not go out as much and/or that they spend more on taxis as a means of overcoming the need for mobility on foot. This leads to suppressed levels of physical activity (with consequent negative impacts on health and well-being) and reduced levels of disposable income, among a group often already experiencing lower than average levels of personal income.

Visually impaired people’s lack of confidence about going out alone or in unfamiliar places results in large part from difficulties with orientation and wayfinding, and the likelihood of becoming disoriented and unknowingly putting themselves in situations of heightened danger. When thinking about this, it is important to acknowledge the diversity among visually impaired people and the variation this leads to in individuals’ coping strategies. For example, researcher Ross Atkin found it informative to group visually impaired people into (1) those who rely on their residual vision, (2) those who use a guiding cane, and (3) those who use a guide dog.

The challenge that emerges is to develop an “environmental information system” accessible to all. Scholar Romedi Passini expresses this as “a coherent ensemble of architectural and graphic cues that provides the decision-making user with adequate wayfinding information at the appropriate place in a form that is both accessible and understandable.” The challenge then for design is how to put together this coherent ensemble of architectural and graphic cues to draw meaningfully on these information channels.

Unfortunately, a lot of the research in this area is old or reliant on small samples. It seems clear that better understanding is needed of what spatial information should be given; in what form that information should be given; at what locations information should be given; and how these vary with key parameters, for example, visual impairment and time and how they relate to various technologies.

Design and Planning Principles

It is well known that risk to pedestrians is increased when road design and land use planning

do not appropriately incorporate the pedestrian by including, for example, delineated footways, controlled crossing points, or adequate lighting. With specific reference to visual impairment, The United Kingdom's (UK) "Guidance on the Use of Tactile Paving Surfaces" sets out five more key design principles:

- Layouts of all pedestrian areas should be simple, logical, and consistent.
- Contrasts in color and tone should be used to accentuate the presence of certain key features.
- Orientation and wayfinding information should be provided by the use of high-visibility and, where appropriate, tactile signing.
- Lighting levels should be even and adequate and should minimize glare.
- Important information about the environment should be conveyed by the use of nonvisual features.

UK industrial designer Ross Atkin, in his findings for a report prepared for the UK Commission for Architecture and the Built Environment (CABE), divides a number of design features into several categories. The first category includes features that benefit all visually impaired people:

- Predictability
- Smooth, even paving, and streets free of obstructions
- Pedestrian-triggered signaled controlled crossings with audible or tactile indicators

Features relevant to those with residual vision include the following:

- Clear tonal contrast (for example, between footway and carriageway, or between street furniture and the surrounding paving)
- Colored paving
- Level surfaces
- Wide footways

Features relevant to visually impaired long-cane users include the following:

- Footways that are not too wide

A wide strip of blister-surface tactile paving alerts visually impaired pedestrians to the beginning of a street crossing in Evanston, Illinois. The use of tactile paving as a warning surface is an increasingly common addition to street surfacing.

- Well-defined curbs
- Tactile paving to alert to the presence of a pedestrian-crossing point or to delineate footways from carriageways where there is not a well-defined curb
- Unobstructed building lines
- Guidance paving in pedestrianized areas and around bus stops or other obstructions
- Guard rails

Features relevant to guide dog users include the following:

- Wide footways
- Well-defined curbs
- Tactile paving to alert to the presence of a pedestrian crossing point or to delineate footways from carriageways where there is not a well-defined curb
- The sound of traffic

Issues of pavement width and the presence or lack of well-defined curbs and tactile paving are points where one group's preferences would appear to be at odds with others. The challenge then is to find ways to resolve these conflicts, and this links to the process of inclusive design. CABE set out five key principles of inclusive design:

1. Place people at the heart of the design process.
2. Offer choice where a single design solution cannot accommodate all users.
3. Avoid steps.
4. Ensure that doors are highly visible and, wherever possible, open automatically.
5. Make space for everyone.

In particular, "placing people at the heart of the design process" means that the process should be one that involves users and, by doing so, seeks to achieve an outcome that includes the widest range of users possible. One crucial aspect of this is the stage at which the blind and elderly community is involved in the process. The danger is that this occurs too late in the process, at which point any case for making changes could be viewed as obstructive and/or to be too substantial to incorporate at that stage.

Tactile Paving

Since its first use in Japan in the late 1960s, tactile paving for the purposes of either hazard avoidance and/or guiding has become increasingly more widespread in its application. It has become commonplace in the UK. The UK "Guidance" sets out seven types, including both warning and amenity surfaces.

The five types of warning surfaces are blister surface (which incorporates flat, round protrusions) for pedestrian crossing points, corduroy hazard warning surface, platform edge (off-street) warning surface, platform edge (on-street) warning surface, and segregated shared cycle track/footway surface and central delineator strip. Amenity surfaces include guidance path surface and information surface.

Whether and how the possibility of seven types of tactile paving can be reconciled with the principle of keeping pedestrian environments simple, logical, and consistent is a contentious point. There

is a view that the multiple types of possible surface lead to confusion among designers and users alike.

Confusion among those implementing the different surfaces has led to inconsistent application, which further accentuates the confusion among users. Hence, amid the moves to develop an international standard there are calls for some simplification.

Shared Space and Shared Surfaces

"Shared space" is an approach to designing streets based on removing the demarcations between pedestrian space and road-user space, on the basis that if the street space is shared, this will naturally lead to greater freedom for the pedestrian and greater caution on the part of motorists. Initiated in the Netherlands, it is beginning to be adopted elsewhere as a means of revitalizing town center areas.

However, it involves some controversy regarding its impacts on pedestrian safety, particularly for visually impaired people, elderly people, and children. In particular, visual impairment advocacy organizations, such as the Guide Dogs for the Blind Association in the UK, strenuously make the case that visually impaired people rely on traditional street design and demarcation in order to keep themselves safe and to orient themselves, and that to remove these aspects leads to increased danger, reduced confidence, and suppressed travel.

Behavior

Driver and pedestrian behavior can also be an important influence on pedestrian safety. Easter Seals Project Action provides simple and useful guidance on behavior intended to promote increased pedestrian safety and access. Its tips for drivers and pedestrians include the following:

- Drivers should be aware that some people might not be able to see your car or move quickly.
- Drivers should be aware of people with service animals and white canes.
- Drivers should be aware that pedestrians and cyclists cannot hear electric or hybrid cars. Be especially careful in parking lots and when backing up.
- Drivers should be aware that loud noises, such as car radios, can impair the

navigation of people using auditory cues for street crossings.

- Pedestrians should wear reflectors and light-colored clothing; small lights and reflective straps are inexpensive and can be found at local bike stores.
- Pedestrians should plan their route and consider all options to travel safely. Traffic and lighting may vary by time of day. The shortest route may not be the safest.

It also warns against driver and pedestrian distraction, be that visual, manual, or cognitive distraction. Given that texting requires visual, manual, and cognitive attention, it strongly warns against texting while driving or walking and, more generally, cautions against use of a mobile phone while driving or walking.

Pedestrian Travel

The generally understood definition of a pedestrian is anyone who walks. And, while pedestrians are everywhere, especially in urban settings, they are often seen not as a major part of the transportation network but as something apart and sometimes even a nuisance.

Pedestrians are, however, an integral part of the intermodal system of transportation. They are not a peripheral entity but are tied very closely to other modes of transportation. Pedestrians affect the planning process that results in the creation and maintenance of transportation infrastructures. The presence of pedestrians affects the movement of people and goods and has significant economic effects.

In 1991, the U.S. government recognized the importance of pedestrians with the passage and signing into law of the Intermodal Surface Transportation Efficiency Act of 1991. Known as ISTEA, this law defined how planning to meet transportation requirements through the use of intermodal means would be done. A key part of this intermodal perspective was the recognition that people walking, especially when that walking is between other transportation points, constitutes an important segment of transportation in the United States.

As might be expected—because government funding, planning, and work on the transportation infrastructure were involved—a legal definition was developed to define what constituted a pedestrian. States (which were also part of planning and implementation processes for ISTEA-related initiatives) and the federal government created those definitions.

In Minnesota, a pedestrian is anyone on foot or in a wheelchair. Ohio's definition reads that a pedestrian is "any natural person, afoot." California's definition include not only people on foot but also anyone operating any human-powered vehicle that is not a bicycle; self-propelled wheelchairs are also covered under this definition. The definition found in Title 23 of the U.S. Code states that any person traveling on foot, as well as any mobility-impaired person using a wheelchair, is a pedestrian.

Pedestrians and the Transportation System

An individual living several miles outside a major city might drive directly to that city to go to work. After reaching their destination, they will park the car and walk to the office. That simple act

of walking has been part of the solution to their transportation problem of how to get to work. Sidewalks or other means of access and infrastructure are needed to be sure people can walk from the parking area to their jobs.

In other instances, walking takes on a more significant and complex role. If people work in an area where there is a public transportation network, their participation as users of transportation infrastructure expands their role. For example, they may drive their cars to a commuter rail station, walk to the station after parking their car, walk from the commuter-rail destination directly to their work destination or to a bus or subway station. Then, they will walk from there to their place of work.

In this expanded scenario, people are using more pedestrian-centered infrastructure, which includes not only sidewalks but also such structures as elevated walkways, transfer stations, and pedestrian areas near train stations, as well as shopping malls and, perhaps, sport venues. In some locations, the use of pedestrian-oriented infrastructure is more intense than in others. In New York City, for instance, it is estimated that less than half of all households have a car. That means that more than half of the population walks as one of their primary means of travel.

Studies of pedestrians and their behavior as a means to support transport planning take on a very high degree of urgency in the current environment and provide a compelling argument for the importance of the research and the subsequent allocation of funds to support it.

Another factor that makes pedestrian behavior and its study so important is the element of safety, which has both economic and societal ramifications. According to the National Highway Traffic Safety Administration (NHTSA), approximately 175,000 pedestrians were killed in motor vehicle crashes between 1975 and 2001. Although the long-term trend has been reduction in pedestrian deaths, they still represent losses in life (affecting society) and have an economic effect in lost productivity, medical bills, and lost wages.

One other factor (potentially significant politically) that bears on the interest in studies of pedestrian behavior is the presence of pedestrian advocacy groups, which are organized to ensure that safe and efficient pedestrian access is incorporated into any new developments, as well as to fight for

restrictions on vehicular traffic that they see as infringing on pedestrian rights.

Finally, a consideration that affects pedestrian behavior, and consequently infrastructure planning and funding, is the special consideration that must be given to guarantee access to disabled pedestrians. Consideration of this segment of the population is not a matter of choice for U.S. governments at any level; the Americans with Disabilities Act (ADA) of 1991 guaranteed that disabled persons would have access to (among other things) the same transportation opportunities afforded to the rest of the population. The Justice Department, often pushed by advocacy groups, has initiated lawsuits in every state to resolve transportation barriers. The city of Sacramento, California, for example, was required spend 20 percent of its annual transportation budget to bring its facilities up to the standards mandated by the ADA.

The act of walking is not simply an individual act, because, for example, if a pedestrian does not get to work, it will have an economic effect on them personally and the society at large. If there is no or inadequate infrastructure that supports pedestrians getting to work, there are adverse economic consequences for companies and the cities in which they are located. The infrastructure support for pedestrian traffic requires a substantial investment, which, in turn, requires intelligent and informed planning. That planning is best carried out with an understanding of the characteristics of pedestrian behavior.

Elements of Pedestrian Behavior

Pedestrian behavior, ideally, should have a major influence in the design of any venue where people will walk, including sidewalks, elevated walkways, pedestrian areas in train or bus stations, airports, malls and shopping centers, and any place where people will gather. In order to effectively research and provide accurate qualitative and quantitative information, however, researchers must first identify and understand the characteristics of pedestrian behavior.

Some analysts have compared pedestrian flow to fluid mechanics, noting the similarities between the flow of people and water, as well as how both can be influenced by obstacles. Based on fluid mechanics, planners learned that creating a zig-zag pattern or using columns in a pedestrian area can break up congestion.

Pedestrians use a crosswalk over double-decker tram rails on a Hong Kong street in 2008. There is a growing awareness that pedestrians are an integral part of the intermodal system of transportation and are closely tied to other modes of travel.

Other analysts note that such an analogy is too simple-minded, especially when considering that potential emotional (for example, panic) factors also come into play with humans that would never apply to water. To one degree or another, however, most agree that physical configuration does play a major role in influencing pedestrian behavior.

There are other factors, however, that affect pedestrian behavior. These include some general, but also sometimes personal elements. The size, health, weight, walking speed of the pedestrian, following distance behind others, and the number of other pedestrians are among the influencing factors.

The reason for the pedestrian's trip affects behavior. Generally, analysts have divided the reasons into three categories. The first is that the trip is required by necessary activities such as work or errands. Second, there are optional activities that take place as opportunity affords, such as going out for a walk on

a nice day. Finally, there are trips to and from social activities that are conducted in public places with other people.

Even the emotional state of the pedestrian (for example, after a win or loss at a sporting event) is relevant. The physical environment in which the pedestrians are walking will also have an effect. Thus, empirical evidence from previous design decisions at other venues will influence design and construction choices later on.

Another aspect of behavior is that influenced by social cues, such as pedestrians deferring to and giving more space to female or elderly pedestrians when they encounter them, even in a crowded situation.

Research on Pedestrian Behavior

While a great deal of pedestrian research has been conducted (with a vast increase since ISTEIA and its successor bills were passed), the discipline is still in an early stage of development and evolution. Until fairly recently, research has taken what is referred to as a microscopic rather than macroscopic view. In other words, earlier studies (and many in progress now) examine the choices of speed and other factors made by individuals.

What researchers are now studying more intensely—falling into the macroscopic category—is the effect groups of pedestrians have. They are studying what influences groups, whether they are people who know one another or simply a cohort group that has spontaneously formed.

How the group shapes itself (into either a convex or concave formation), how much space it has between members, and how that group navigates clear spaces and bottlenecks are coming under increasing study. In any event, there is validity in both approaches, whether the individual is studied as part of a larger transportation flow (macro) or as an individual agent who may affect the larger flow (micro).

Whether individuals or groups are studied, there are several considerations that must inform the study if it is to be successful. Among these are a picture of the personal characteristics of pedestrians, time of day, reasons for the trip, properties of the infrastructure being used, and environmental considerations such as the weather and season.

The immediate circumstances in the pedestrian area are also significant. Planning for many baby

strollers on a Sunday afternoon will be different from preparing for masses of rush-hour walkers. In the event of an emergency (that is, panic situations), the dynamic will again be altogether different.

The methodology for studying and analyzing pedestrian behavior is usually mixed, and there is a great deal of literature in the academic journals concerning new methods to more accurately measure and predict pedestrian behavior. Observation of some sort is essential, many times taking the form of videotaping a pedestrian area. Software to support analysis based on observations of trends and patterns, as well as simulation software, is increasingly used.

There is also a growing awareness that an important element in research is an ethnographic component. Cultural differences in when people go to work and return home, the speed with which people walk, the amount of space that they maintain between themselves and others, and their tendency (or not) to stop on the way home are all factors that are increasingly being considered. Researchers understand that the differences between pedestrian behaviors in Hong Kong, London, Warsaw, or Boston are potentially major factors to be considered as part of transport planning.

Pedestrian-Friendly Design

Walking is more than simply a utilitarian function. It, in fact, characterizes the very essence of human life. Walking offers various economic, environmental, physical, and social benefits at various scales. At the regional level, it plays a critical role in multimodal transportation systems by linking various modes of transport. At the neighborhood level, it contributes to the quality and vibrancy of community life. At the individual level, it contributes to increased cardiovascular fitness, reduced stress, stronger bones, and mental alertness. Also, walking contributes to inclusive mobility, as it is considered a more equitable mode as most everyone can walk (including those below driving age), while not everyone can drive.

However, the levels of walking, and the potential for making important trips by foot or in combination with other modes, have dwindled and are further threatened by the increasing levels of motorization. In communities where vehicles have become the priority over pedestrians, streets are perceived to be unsafe for walking. But with renewed efforts toward developing more sustainable and safer communities, alternative approaches such as improving the built environment to be more pedestrian friendly are one key strategy to encourage more walking. Pedestrian-friendly design helps enhance the built environment. It is also an effective way to encourage walking, attract more pedestrians, and promote higher levels of pedestrian travel.

Pedestrian-friendly design of streets contributes to the economic vitality of cities. Recent research has shown that well-designed and maintained pedestrian facilities and pedestrian-friendly streetscape improvements have increased retail sales in urban centers. More specifically, a study in Toronto has shown a decrease in vacancy rates while bolstering property values when pedestrian-friendly features were introduced. Moreover,

people who live in neighborhoods with higher levels of density, a mixture of land uses, access to public transit, and pedestrian-friendly features tend to use their private car less than residents in neighborhoods that lack these attributes. Enhancing pedestrian-friendliness in neighborhoods is a positive planning factor that provides multiple benefits.

Empirical evidence is not yet complete but a number of studies have consistently found a strong relationship between the characteristics of the built environment and levels of walking. As an example, a study that looked at the effects of site design on pedestrian travel in mixed-use medium-density environments found that locations that provided facilities and direct routes for pedestrians resulted in higher incidence of walking. Similarly, a University of Washington study confirmed that site design and community layout, as well as the presence of well-designed and maintained pedestrian facilities, are elements that can potentially predict pedestrian volumes in suburban locations.

While evidence suggests that the availability of pedestrian facilities encourages walking and attracts more pedestrians, it is also true that when pedestrian access is expanded and existing conditions for pedestrians are significantly improved, through the inclusion of pedestrian-friendly design, higher numbers of pedestrians can be expected to use the system not only to undertake necessary activities but what Jan Gehl categorizes as desirable and social activities, thereby promoting higher levels of pedestrian traffic and activities.

Design Features

Pedestrian-friendly design is a built environment-related strategy that assists in enhancing the physical environment and increasing the amount of physical activities, including walking. In this regard, the planning and design profession is in an important position to better understand and cater to the improvement of the pedestrian environment and encourage active travel. Pedestrian-friendly design is a key tenet in urban design and planning for compact cities, smart growth, transit-oriented developments, and new urbanism. For example, the “new urbanism” movement, a group comprised of proponents who advocate walkable neighborhoods, proposed the following elements as contributory to a more pedestrian-friendly environment: mixed-use

streetscapes with corner shops, the provision of diverse housing types that incorporate neotraditional neighborhood design, and design that ensures proximity to public transit. These elements, they claim, enhance mobility of residents and provide an environment that is safe for walking. In addition, pedestrian-friendly design considers pedestrians to be the most important entity when planning for transport. This is further espoused by what scholar Todd Litman connotes as the “green transportation hierarchy.” This concept proposes that pedestrians must be at the top of the road user hierarchy, implying that pedestrians are the most important entity in planning for streets.

Reid Ewing, author of *Pedestrian and Transit-Oriented Design*, a joint publication of the American Planning Association and the Urban Land Institute, suggests 28 pedestrian-friendly design features that can be categorized into three groups. These include (1) essential features perceived to be critical to the success of pedestrian-friendly sites; (2) highly desirable, though not mandatory, features that contribute to bettering the pedestrian environment; and (3) nice additions, not essential but worthwhile having within pedestrian-oriented locations. Essential features include medium-to-high densities, a mix of land uses, short-to-medium-length blocks, regularly spaced transit routes, two- or four-lane streets, continuous sidewalks wide enough for couples, safe crossings, appropriate buffering from traffic, street-orientated structures, and comfortable and safe places to wait.

Density is seen to be a critical feature to support pedestrian-oriented environments. Density, specifically residential density, is seen as an important and critical predictor of nonmotorized travel. A sufficient density and concentration of people can support a variety of activities colocated within a relatively small zone, which can then be accessed by walking. High densities are achievable in communities by promoting small-scale buildings with high lot coverage.

A mix of land uses that accommodates pedestrian-supportive land use patterns is also a plausible and practical strategy to increase density, attract pedestrians, and support pedestrian activities. One example is the combination of complementary functions such as commercial and retail with residential. There are, however, certain land use patterns that are unsuited to walking, such as poor access design

to and within developments, better access to cars than public transport, and inconvenient or unpleasant pedestrian facilities.

Pedestrian safety is also one of the major concerns when designing for pedestrian friendliness. For example, by providing safe crossings and safe places to wait, pedestrians' perception of walking as being risky is minimized.

A complete system of interconnected streets, pedestrian walkways, and other pedestrian facilities provides a continuous and seamless walking path between origin and destination, ensuring good pedestrian circulation and access, especially to highly used origins and destinations. Compact and well-connected land uses are related to lower vehicle miles traveled (VMTs) and lower emissions of ozone precursors.

Pedestrian-oriented schemes such as creating active frontages to local area retail and commercial venues are important strategies that encourage pedestrian presence, serve as a territorial passive surveillance approach, and thereby contribute to an overall better pedestrian experience.

Ewing mentions a number of highly desirable features: commercial land uses, grid street network, traffic calming along access routes, closely spaced shade trees, minimal dead spaces, parks and public common spaces, small-scale structures, and pedestrian transit facilities. While not mandatory, he also mentions "nice" attributes to include: streetwalls, functional street furniture, coherent signage, special pavement, and public art.

Risks and Benefits

While proponents of a pedestrian-friendly environment have continually stressed its positive values, some authors have also pointed out its associated risks. As an example, the increased levels of outdoor physical activities may also be detrimental to one's health given the increased exposure to air pollution and traffic hazards. It is, therefore, crucial to combine expected lower vehicle miles traveled with a significant shift to nonmotorized modes of travel to significantly counteract the potential for increased exposure to associated environmental risks.

Whether pedestrian friendliness of the built environment influences walking or an individual's preference for active travel impacts their choice of a residential location, the need to enhance the quality of place by introducing pedestrian-friendly

features helps support higher pedestrian patronage. It has been documented that a well-designed physical environment continues to influence residents' physical activities. Thus, people should be more physically active and more likely to use active transport modes such as walking in an environmental context that offers continuous and well-maintained walkways, a gridded street network, well-lighted paths, greater safety, proximity to destinations, and an attractive walking environment.

People Movers

People movers are a type of automated transit system that transport passengers via driverless vehicles along fixed routes. They may be implemented for purposes as simple as transporting passengers along short routes such as from terminal to terminal in airports (and the motorized walkways used in some airports are essentially the simplest version of such systems) to intracity and intercity transit. Because the drivers' salaries and benefits are the largest part of the operating cost of a rapid transit system, automated systems are ideal for implementations such as free transit service (such as in airports or some

cities) and transit in areas that cannot afford greater operating costs.

Most people mover systems use automated guideway systems that employ a guide such as a rail or other system in order to both provide physical support for the vehicles and direct the vehicles along their route. Like most conventional guideway transit systems (subways, trains, and streetcars), they are grade separated, meaning that they are separated by height from other transit routes so as to not interfere with traffic flow. In confined areas such as airports this is accomplished easily by building a rapid transit system route that skirts the perimeter of the passenger-accessible areas without cutting off pedestrian traffic flow. In other areas, more planning is required.

History

The earliest significant automated rapid transit system was built for the 1924 British Empire Exhibition, a globally touring exhibition of British culture and technology meant to stimulate trade between the British and the 58 countries of their empire. On the London stop of the tour, the “Never-Stop Railway” was constructed to bring passengers to various parts of the exhibition. It deployed 88 driverless carriages on a continuous track on parallel concrete beams, with pulleys guiding the carriages. A revolving screw thread propelled the carriages and adjusted the speed in order to slow carriages down as they approached disembarkment stations. The railway ran for two years.

Automated systems that service airports, commercial districts, and theme parks are often called people movers, a term originally applied in the 1960s to such systems developed by Goodyear and the Expo 67. The term reflects the purpose of the system rather than its design, which may be based on cable traction, linear motors, or conventional electric motors. Smaller systems are usually categorized by themselves, as personal rapid transit systems (PRTs). Intense development of automated rapid transit systems began in the 1960s amid growing concerns about urban congestion, population growth, the pollutive effects of car ownership, and the effects of suburban sprawl. Numerous concerns, ranging from the environmental (seeking to limit emissions by encouraging development of public and mass transportation) to the commercial (making tourist areas and shopping districts more easily accessible), motivated

development throughout the world. Though subway systems continued to be expanded in urban areas, much of the people mover development focused on using elevated tracks, which were cheaper to deploy and faster to construct. These automated people mover systems had numerous appeals, including reduced operating costs and the practicality of fixed routes, to urban planners.

Mid-1960s legislation led to the funding of federally developed automated transit systems under the 1966 Downtown People Mover Program. Ford Motors, Otis Elevator, aerospace company Rohr (now Goodrich Aerostructures), and aerospace firm Ling-Temco-Vought all developed systems in the next few years and exhibited prototypes in the early 1970s. Like many initiatives born in the early 1960s and 1970s, though, enthusiasm and support soon waned, and like many advances in transportation, they saw little development in the 1980s.

Operating People Mover Systems

One of the few automated transit systems successfully developed in the Downtown People Mover Program was the Metromover, which began operations in Miami, Florida, in 1986, 20 years after the program’s creation. The Metromover expanded its route coverage in 1994 and now offers free transportation to 32,000 riders a day, connecting downtown Miami and the neighborhoods of Brickell, Park West, and Omni. The Metromover serves 21 stations, each about two blocks apart, and can bring passengers within a short distance of any building downtown. It is integrated with the paid Metrorail system through two stations, at Brickell and Government Center. The Metromover is today one of only three people movers used for downtown public transit in the United States, and it is the most comprehensive of the three. It set a daily ridership record for people movers in 1987, just after finishing its first year of service, and has been free since 2002 (when it was discovered that the cost of collecting fares exceeded the revenue generated). The operating cost averages roughly \$1.02 per ride, based on fiscal year 2007 figures, but the economic benefits to the Miami community are believed to be substantially greater.

The vehicles used by the Metromover are a combination of Adtranz C-100s and Bombardier Innovia APM 100s, both of which are developed by the company now known as Bombardier Transportation

(formerly Westinghouse Transportation Services, AEG Transportation, and Adtranz). The C-100 was first deployed at Tampa International Airport in 1971, and most C-100s today are used for intra-airport transit, as are most CX-100s, the official model replacement for the now-deprecated C-100 design. Airports using either C-100s or CX-100s include most of Florida's major airports, London Gatwick Airport, Hartsfield-Jackson Atlanta International Airport, and Seattle-Tacoma International Airport. The Innovia APM 100 is also based on the C-100 designs and debuted at Dallas-Fort Worth International Airport in 2005.

The other successful system developed under the Downtown People Mover Program is the Detroit People Mover (DPM), the developers of which persisted despite cuts to funding in the 1980s and a scaling back of original goals and intentions. It began service in 1987, shortly after Miami, and continues to operate. It may be deemed less successful than the Metromover by most measures, serving primarily out-of-towners, with operating costs half again as high as the Metromover's, despite a much lower ridership (7,500 riders a day in fiscal year 2008). The DPM serves 13 stations in a loop, using 12 ICTS Mark I cars made by Bombardier.

The only downtown people mover program in the United States that did not originate with the 1966 People Mover program is Florida's Jacksonville Skyway. An automated monorail serving eight stations, the Skyway has been extended three times since beginning service in 1989 with three stations. Currently, it operates two routes, with a daily ridership of about 1,300. It has been widely criticized for attracting a lower ridership than projected, even after route extensions intended to increase usage.

Urban people movers are somewhat more successful outside the United States. Vancouver's SkyTrain system in Canada is the largest automated transit system serving a metropolitan area. It consists of 42.7 miles of grade-separated track, primarily on elevated guideways, divided into three operating lines with a fourth under construction. The SkyTrain began operation in 1985 and today includes 47 stations, with a daily ridership of 396,500—more than the combined ridership of all downtown-serving automated transit systems in the United States—and close to the annual ridership of Jacksonville's system. Its operating fleet consists of 298 cars, which travel between 40 and 55 miles per hour. It is operated by

The Detroit People Mover (DPM) at Times Square Station, one of the system's 13 stations, which are connected in a loop. In 2008, the DPM had a ridership of 7,500 riders a day making use of 12 ICTS Mark I cars manufactured by Bombardier.

several companies under contract with TransLink, the regional Canadian transportation agency, and shares a fare system with other transit services in the region, allowing passengers to pass back and forth through different services for the sake of route flexibility. The 2008 operating costs were \$83 million, but advertising alone brought in \$360 million in revenue, with additional revenue provided by a transportation fund drawing on fuel and property taxes. The SkyTrain has had a considerable effect on the development of metropolitan Vancouver in the last 25 years, with over \$5 billion in private money invested in developing areas within a short walk of SkyTrain stations, and the population of the service area rising from 400,000 when the service began to 1.3 million in the most recent census, a threefold increase.

Outside of such downtown areas, automated rapid transit systems are common in theme parks, international airports, and large hospitals. But one of the most important types of implementation has been the adoption of automated rapid transit in smaller cities that have trouble sustaining the

operating costs of a transit system. Many smaller French cities, for instance, have adopted automated metro systems, as have the Italian city of Perugia and a number of Asian cities.

Personal Rapid Transit

Personal rapid transit (PRT) systems are a subset of automated guideway transit (AGT) systems, at the smallest end of the capacity spectrum. Recent plans for PRT systems have sometimes used the terms *podcar* or *pod*. While typical people movers, another form of automated transit system, are often similar in capacity to traditional buses or train cars, PRT systems transport either individuals or small groups of up to six people. The vehicles are considerably smaller than those used on other automated transit systems, no more than 20 feet long and 8 feet wide, with a maximum travel speed of 20 miles per hour. Typically, PRT systems are used for direct routes from one point to the other, with no stops along the way. PRT systems are sometimes compared to automated taxis, but because they follow a guideway, they lack the flexibility of an automobile.

PRT systems are driverless, traveling along an aerial or underground guideway system. Because payroll is the biggest annual expense in transit

systems, automated systems reduce costs of transit and make it financially feasible to offer free transit in certain situations. For instance, automated systems are used in many airports, which assists in airport layout by reducing the time it takes for passengers to arrive at a given terminal. However, because they carry only a few passengers at a time, PRTs can offer more flexible types of service.

After years of attempts at developing PRT systems, most of which were failures, the Advanced Transit Association (ATA) in 1988 created a set of guidelines defining what is meant by PRT, as opposed to other transit systems. PRT systems are fully automated and operate on a dedicated guideway, either underground, at ground level, or aboveground. They are small vehicles available 24 hours a day for one to six passengers. A PRT vehicle is able to access all the guideways and stations on a fully coupled network. Service is direct, without transfers or stops. Service is available on demand. Ideally, a PRT system offers the same access to the elderly and disabled as other transit systems do; though this is not specified in the ATA guidelines, it can be inferred from the Americans with Disabilities Act.

PRTs were one of the many transportation concepts that developed in the tech and engineering boom that followed World War II, in part as a result of the amount of resources and attention devoted to training engineers in the war years and subsequently in the Cold War, and in part because of the baby boom, a subsequent housing boom, and the changing layout of the country. The federal government began funding studies to develop automated transit systems, including PRTs, in the 1960s, and in the 1970s numerous transit possibilities competed for attention, funding, and planning committee preference, including PRTs, monorails, refinements to existing subway and bus systems, automated walkways, and other solutions to increasingly urban and suburban American life. The rapid rise of car ownership and driving in the same period was in some part a response to the delays that prevented transit solutions from being implemented earlier, and in part exacerbated those delays by reducing demand for public transit. As the relatively affluent middle class expanded, two-car households became more common, contributing to the tendency of suburb developers to leave transit needs barely addressed except for the question of how to get children to school.

New Technology

Apart from a few outliers that do not quite fit the ATA definition, the PRT concept may have died on the vine, at least in the United States, if not for the personal computing revolution. While the splash personal computers made is remembered now principally as being responsible for bringing computers into the home and making computer users out of computer novices, the technological revolution that was transpiring ushered in today's age of computing ubiquity. The advances that allowed computers to fit on a desk top and use a modified television as a display also allowed computers to be used for applications that previously would have been impractical. Over the course of the 1980s, the amount of computing power and memory a single device was capable of increased more dramatically than in the entire history of computers to that point.

The computer revolution changed engineering by allowing engineers to design and model systems more accurately and efficiently, while offering new possibilities for the design of control systems. Subways, buses, and other transit systems soon added magnetic-strip-based fare cards rather than the labor-intensive pass or token system of the past, and it became easier to automate other systems as well. As it did, interest was revived in PRT, leading to the discussions that culminated in the ATA's meeting. In the meantime, transit engineers and planners had learned from several decades of intensive development in a variety of communities and implementations and now had a more sophisticated sense of the populace's transit needs and of the various uses of transit systems.

On-demand service is one of the key differences between PRTs and other people mover systems. Airport people movers frequently operate on a fixed schedule: they make a circuit of the airport, stopping at each stop for about two minutes while passengers disembark or board, and do so continuously. A PRT system operates more like an elevator, but without stopping at any floors but one's own, and when not in use may either remain idle or return to a particular station, depending on the needs of the system and the purpose it serves.

PRT systems are largely hypothetical, especially going by the ATA definition. Plans for a 40-car PRT system in Suncheon, South Korea, have been delayed after an expected 2013 launch. A 10-vehicle system operates in Masdar City, United Arab

Emirates, though it has remained in the pilot stage and its announced expansion was canceled. A 21-vehicle system at Heathrow Airport in London opened in 2011 and is expected to expand. The Heathrow PRT system is developed by ULTra Global PRT, a British engineering firm branding its system as ULTra (Urban Light Transit). The electric vehicles are four-seaters with a travel speed of 25 miles per hour, a little faster than most PRT systems, and have accommodation space for wheelchairs, shopping carts, and luggage.

The pods are battery-powered and, following the ULTra design philosophy to use off-the-shelf technologies whenever possible, they use four car batteries, accounting for 8 percent of the vehicle weight. This makes for easier deployment and installation than a system that draws power off the grid, as streetcars do.

The first test track of ULTra was launched in 2002 with \$4 million in funding from the British government. Though the vehicles can handle a gradient of up to 20 percent, for passenger comfort the company recommends no greater a gradient than 10 percent. In some applications this means installing an elevated guideway in order to avoid steep ascents. ULTra was installed at Heathrow in 2010, operating 22 hours a day, seven days a week. It takes passengers from the business passenger parking lot to Heathrow's Terminal 5, 2.4 miles away. Over its first year, average passenger wait time was 10 seconds, and the system operated with greater than 99 percent reliability. It uses less than half the energy of a bus system. The planned expansion will connect parking lots to Terminals 2 and 3, and plans are considered to connect the airport to nearby hotels. ULTra has also conducted a pilot project in India.

Morgantown Example

In the United States, the Morgantown Personal Rapid Transit system has operated since 1975, connecting the central business district of Morgantown, West Virginia, to the three campuses of West Virginia University. The system covers 8.7 miles and five stations, with a daily ridership of 16,000. Development began in 1970 with a government grant to fund an experimental PRT system, and launched operations five years later. At the time it was one of many PRT experiments throughout the country, but most never saw the light of day. Over its history, it has operated with 98.5 percent reliability.

An ULTra PRT pod in a Heathrow Airport parking facility takes passengers 2.4 miles to an airport terminal in 2012. The system uses less than 50 percent of the energy of a bus system and has achieved 99 percent reliability.

Boeing, Bendix, and the Jet Propulsion Laboratory were all involved in the development of the Morgantown PRT, which was built around the Alden staRRcar system. Unlike the ULTra system, the vehicles are powered by electrified rails like many subways, driving a 70-horsepower direct current motor. In the 2000s, when Morgantown became famous for having the lowest unemployment rate in the United States, the mayor credited the PRT system for allowing the city to grow. In the late 1990s, the original DEC PDP-11 computers used to control the system were replaced with Intel Pentium devices.

By the ATA definitions, the Morgantown PRT system is not a proper PRT system. The 15.5 by 6.6 feet vehicles accommodate up to 20 people (with eight seats and standing room for the rest), and in fact there is an annual college student event called

the PRT Cram in which student organizations compete to fit as many people as possible into a PRT car (2000's record of 97 has not been beaten). Further, when there are more than a few people, the car becomes a normal people mover, going from one stop to the next instead of taking its passengers on a nonstop direct trip.

Because it can and does act like a PRT system for part of the day, the Morgantown system may be thought of as one that switches between a PRT system and a normal people mover, in response to conditions. During peak hours, when cars carry larger numbers of passengers, it operates in schedule mode, following a fixed route. During off-peak hours, the system operates in both demand mode and circulation mode.

In circulation mode, a smaller number of vehicles follow a fixed circuit, stopping at every station. In demand mode, when a rider requests a car through a call button, a vehicle is activated either after a specified period of time (usually five minutes) or once enough passengers have requested service, whichever threshold is passed first. Because it does not run late at night or on Sundays, it also fails the ATA's 24–7 requirement. Systems like Morgantown's, which are influenced by PRT designs but differ from the typical PRT in capacity, are sometimes called Group Rapid Transit.

Benefits

Ideally, the strength of a PRT system beyond its efficiency and low operating cost is its passenger-driven demand-based approach. The more stations the system serves, the more this is an advantage to the passenger, who can travel to any station directly, with minimum waiting and travel times. The small capacity of the cars also means that a larger share of the cars travel at full capacity, increasing their operational efficiency. The smaller vehicles also mean the guideway and right-of-way requirements are substantially smaller than for other forms of transit—this is especially true at the small end of the spectrum like ULTra's podcars, but even Morgantown's system has reduced space requirements compared to a subway system. These reduced requirements make planning and implementation easier, and increase substantially the existing spaces into which a PRT system can fit.

That ease of planning fits well with what ULTra and other systems have shown—that a healthy and

effective PRT system can be constructed with off-the-shelf technology. This means firms can design and deploy PRT systems with less human and intellectual capital, not only reducing costs but reducing the amount of time it takes to develop such a system. The main source of delays in deploying and expanding ULTra, for instance, have been at the customer end of the relationship, because of the bureaucracy involved and the planning sessions that precede such decisions.

PRT systems also have the advantage of being able to be implemented incrementally; by their nature, they are well suited to expansion, which should encourage communities to be willing to adopt them on a small scale without worrying that they need to debate the merits of a larger-scale implementation first.

While PRT systems outside Morgantown have mainly been implemented to serve specific commercial purposes, such as transit to or within the grounds of an airport, they have potential as primary transit systems. PRT systems are more affordable and within the reach of smaller cities like Manchester, New Hampshire; Billings, Montana; or Denton, Texas, which are too small to warrant other rail systems but which would benefit from increasing their city's transit accessibility. PRT systems can also augment existing transit systems, providing feeder systems from outlying communities or targeting specific routes or populations, such as on-campus student residents, retirement communities, or new residential neighborhoods.

Conclusion

Before the worldwide financial crisis of 2008, there were several plans to develop or pilot PRT systems in various American communities, notably as part of the Skyloop in Cincinnati, Ohio, and in California's Silicon Valley. The subsequent depression canceled, delayed, or postponed many of these plans, and while the federal stimulus package of 2009 earmarked about \$27 billion for transportation projects, states chose to spend most of this money to build new roads and other motor vehicle infrastructure. Since then, however, the ULTra system at Heathrow has brought attention to the concept, and progress has slowly begun again.

Personal Transportation Systems

A personal transportation system is one that transports only the driver or operator, without passengers or freight (beyond what is carried on the person, such as a backpack). This can include bicycles and other human-powered devices, and is especially used to refer to motorized single-person transporters such as the Segway PT, introduced in 2001.

The Segway PT was one of the most highly anticipated new products at the time of its release, because of a powerful prerelease publicity campaign that did not even reveal the name of the product, referring to it only as "IT." Much of the publicity was inadvertently blown out of proportion after leaks from an unreleased book about the Segway's development, which, out of context, made the device seem more significant than it was prompted a hype-prone press to speculate that IT, whatever it was, would be as culture-changing as the Internet or the personal computer had been.

The public unveiling was televised on *Good Morning America*, and IT was revealed to be a motorized one-person platform with gyroscopic and leveling sensors to both keep the device upright and allow the operator to steer the device by shifting weight forward or backward. Steering is accomplished via a handlebar. Speeds approach 12 miles per hour (mph).

A wounded veteran stands on a Segway personal transportation device at a demonstration for the U.S. Marine Corps in Arlington, Virginia, October 6, 2010. A group called Disability Rights Advocates for Technology has pressed for more communities to maintain sidewalk and building access for personal transporters as a requirement of the Americans with Disabilities Act (ADA). In 2011, an amendment to Title II of the ADA led to Segway use being permitted under the class of "other power-driven mobility devices."

The Segway is electric and uses lithium-ion batteries, which are recharged by plugging into an ordinary household outlet. They have not been approved for marketing as a medical device, and they cannot be sold as one for insurance purposes. Dean Kamen, the Segway's inventor, sold the medical rights to the underlying technology (originally used in the iBOT self-balancing wheelchair) to Johnson & Johnson, preventing him from pursuing this route with the Segway.

Nevertheless, the Segway, like other personal transporters, has found a following in the disabled community, and the group called Disability Rights Advocates for Technology has pressed for more communities to maintain sidewalk and building access for personal transporters as a requirement of the Americans with Disabilities Act (ADA). On the other hand, the American Council of the Blind has

opposed efforts to increase Segway use, arguing that their use creates an environment that is more dangerous for the blind and makes collisions—which, while frightening, rarely lead to injury when they are between pedestrians—more serious, because of the increased weight and, especially, the higher speed of the Segway in comparison to a human.

In 2011, an amendment to Title II of the ADA permitted Segway use under the class of "other power-driven mobility devices," without reference to the medical-device criterion. However, not all jurisdictions have updated their laws to include this class, and the amendment provides some leeway in interpretation.

Personal transporters are widely used by police and private security forces, and they are sometimes rented to tourists in theme parks and other similar attractions as an alternative to pedestrian

travel. Personal transporters are usually considered a means of travel suited to sidewalks rather than streets, although the legality of street travel depends on the location.

The motorized personal transporter does not generally require a license or vehicle registration, though an age restriction on the operator may apply. In some jurisdictions, Segways are classed as vehicles or alongside another vehicle type. For example, in Japan and Switzerland, it is considered a type of motorcycle; in much of central and eastern Europe, it is grouped with bicycles and pedestrian traffic, and where one is legal, so are all three; Denmark classifies motorized personal transporters as mopeds, requiring mechanical brakes, lights, and a license plate; and Sweden has classified personal transporters as bicycles since 2010, having previously banned them on public pavement (whether road or sidewalk).

In North America, personal transporter policy is left to local authorities. Few Canadian provinces permit personal transporters on public roads, limiting them to private property. In some jurisdictions, they are not even allowed in bicycle-designated areas such as paved bicycle paths. The province of Ontario has operated a pilot program permitting Segway street access to people who are disabled, postal carriers, and police officers, but participation has been low.

In the United States, the Segway's inability to be classified as a medical device has led to its default ban from sidewalks and on public transportation in many areas where medical devices are the only forms of transport exempted. Few states ban their use on sidewalks, leaving the matter for individual municipalities to decide. Most states either permit the use of Segways in bicycle lanes, on bicycle paths, and on roads with a posted speed limit of 25 mph or lower, or do not specifically ban them; again, within each state, individual municipalities may, and often do, pass more restrictive regulations. In some cases, use of Segways in public areas is limited to daylight hours.

In Disney-branded theme parks, personal Segways and other personal transporters (if not classed as medical devices) are banned, but the parks provide guided Segway tours for a fee. This approach has been adopted by other theme parks.

The Segway is the market leader in motorized personal transporters, and the name has become,

to a large extent, the default term for them. However, other brands are available. Honda's U3-X released in 2009 is a self-balancing, one-wheeled vehicle based on technology originally developed for a bipedal human-like robot. It is smaller than the Segway and fits between the operator's legs, but also has a much lower speed, comparable to fast walking (about 3.7 mph). The Toyota Winglet, developed at about the same time but not yet released to consumers, is similar, using two wheels but achieving the same speeds as the U3-X. In 2012, Personal Rover released its device, which is similar to a motorized skateboard with handles resembling ski poles that are used to maneuver. This product is available at a lower price point than most of its competitors.

Personal transportation systems also include powered wheelchairs and mobility scooters. Mobility scooters have become popular choices for the elderly and those with significant arthritis or respiratory issues who are capable of mobility but benefit from assistance or tire quickly, particularly in circumstances like shopping or visiting parks. Many supermarkets and malls now provide mobility scooters of three-, four-, or five-wheel designs. This service is especially beneficial because Medicare does not pay for powered wheelchairs (of which scooters are considered a subset) for individuals who do not need them inside the home.

Several single-person cars are subject to the same safety regulations as other automobiles. They include the Formula Ford race car, a training race car with safety modifications to make it street legal; the Exomotive Atomic, which resembles a small low-riding dune buggy and has the motor in the passenger space; ultracompact vehicles like the open-design SUB Motorsports three-wheeler (resembling a kayak with wheels); and riding lawnmowers modified to meet road-use regulations. Hitachi has also developed the Ropits (robot for personal intelligent transport systems), which provides sidewalk transportation for the elderly and disabled in the form of covered self-driving motorized scooters.

Pipeline and Hazardous Materials Safety Administration

The Pipeline and Hazardous Materials Safety Administration (PHMSA) was created under the Norman Y. Mineta Research and Special Programs Improvement Act of 2004 as an agency of the U.S. Department of Transportation (DOT). PHMSA is responsible for creating and enforcing regulations to ensure the safe and dependable operation of the country's more than 2-million-mile natural gas and hazardous liquids pipeline transportation system. It also has regulatory oversight of the daily volume of nearly 1 million hazardous materials shipments carried by land, sea, and air across the United States. The regulations are designed to protect people, the environment, and the transportation industry from risks associated with the transport of hazardous materials.

Hazardous materials quite literally fuel the U.S. economy and are essential to maintaining quality-of-life standards. Oil and natural gas are used to produce electricity, heat and cool residences and businesses, transport people and products, and provide feedstock for a number of other commodities. Hazardous materials are also used in the purification of drinking water for human consumption, fertilization of agricultural crops, production of pharmaceutical drugs, and manufacture of apparel and other goods.

Relying on hazardous materials for so many critical functions comes with risks, especially those

associated with transporting hazardous materials from one location to another. The PHMSA regulations are designed to protect people, the environment, the transportation industry, and the economy from those transit-related risks.

Structure and Role

PHMSA is headquartered in Washington, D.C., and has regional representation across the United States. Operations are divided into two designated safety offices—the Office of Pipeline Safety and the Office of Hazardous Materials Safety—which are overseen by an administrator appointed by the president. Support is provided by a senior leadership team and nearly 500 employees agency-wide.

PHMSA's primary focus is on safety. Among its key responsibilities are establishing national hazardous materials transportation policy, and setting and enforcing standards designed to eliminate deaths, injuries, incidents, and damage to the environment and property as a result of hazardous materials conveyance. PHMSA also works to reduce dangers and harmful consequences to individuals, the environment, the transportation industry, and the economy at-large following a hazardous materials accident or pipeline failure. In the case of states, communities, and population groups that require financial and technical assistance to become prepared for hazardous materials emergencies, PHMSA awards special grants.

The organization proactively sponsors research projects related to advancing technologies that have potential application for enhancing hazardous material and pipeline safety procedures. PHMSA also distributes special permits, guidance documents, and informational materials to improve education, and administers a toll-free telephone information center that enables anyone to ask questions, order publications, and report safety violations of PHMSA regulations. For travelers, the agency provides continuously updated safety guidelines regarding personal transportation of materials that may be hazardous or contain hazardous components, such as batteries and battery-powered devices.

Outside the United States, PHMSA participates in an ongoing initiative aimed at standardizing pipeline and hazardous materials transportation requirements across the globe. It also works with agency counterparts in Canada and Mexico to coordinate consistent North American guidelines

for firefighters, police, and other emergency services workers who are likely to be among the first responders to a hazardous materials accident. At U.S. ports of entry, PHMSA facilitates the safe and orderly transport of hazardous materials.

In the area of enforcement, the organization conducts drug and alcohol testing of personnel who transport hazardous materials, and ensures compliance with safety and training standards by way of conducting field inspections of shipper and carrier transportation facilities; manufacturing, packaging, repairing, and reconditioning work areas; cargo vessel ports; rail freight yards; motor carrier and air cargo terminals; and chemical and explosives manufacturing plants.

Accomplishments and Challenges

Through the work of the DOT, and later joined by the efforts of PHMSA, the risk of hazardous materials transportation incidents resulting in death or major injury was reduced by 4 percent every three years between 1988 and 2011. Similarly, the risk of pipeline incidents leading to death or major injury was lowered by approximately 10 percent every three years in the same timeframe. Since 2002, the risk of hazardous liquid pipeline spills with environmental consequences has receded by an average of 5 percent each year.

Building on its long history of success, PHMSA set stringent safety and environmental goals to achieve by 2016. Specifically, the agency seeks to further reduce the number of fatalities and serious injuries from hazardous materials and pipeline incidents each year to below 38. It also wants to reduce environmentally damaging hazardous materials and pipeline incidents each year to less than 65 and 82, respectively. To achieve its goals, PHMSA will have to address a number of challenges in the areas of infrastructure, product evolution, technology advances, and human factors.

With population growth, energy consumption, and chemical production expected to rise, the exposure to risk from incidents involving hazardous materials and pipelines is also likely to rise. The U.S. Department of Energy (DOE) forecasts a potential 13 percent to 27 percent increase in risk exposure through 2015.

PHMSA is adapting to the growth and geographic shifts in population by requiring businesses to account for population exposure through their own

risk management programs, meaning that pipeline companies must consider population exposure as part of their integrity management programs and when classifying lines for transmission of natural gas. In addition, PHMSA has put hazardous materials transit through high-population areas under closer scrutiny, with stricter technical requirements, route restrictions, and safety inspections.

With approximately 17 percent of natural gas and hazardous liquid pipelines greater than 50 years old or of unknown age, and another 8 percent constructed of erosive materials, the pipeline infrastructure itself poses another challenge for PHMSA. The agency works with state pipeline safety programs and pipeline operators to accelerate the identification, repair/replacement, and requalification of the pipelines posing the highest risks. It is also researching new technologies designed to enhance the ability to identify, assess, and control pipeline risks.

Among the leading causes of safety incidents resulting in death or major injury are pipeline material failure, corrosion, and damage to pipeline integrity from excavation or another external force. To reduce the occurrence of compromised pipelines from such causes, PHMSA has expanded its safety inspections, targeted research, and established the 811 Call Before You Dig program, which encourages excavators to call for information before they break ground. The organization also is proactive in promoting best practices regarding land use planning and development near transmission pipelines.

Crashes and rollovers involving tank trucks carrying gasoline and other flammable liquids account for approximately three-quarters of gasoline-related fatalities, and they rank as a leading cause of injury and death from hazardous materials transportation. Such accidents also can result in spills that prompt highway closures and environmental contamination. PHMSA works with the National Highway Traffic Safety Administration and the Federal Motor Carrier Safety Administration to draft standards for electronic stability control for trucks, and with other DOT agencies to provide enhanced tank-truck driver training, as well as to find ways to reduce driver fatigue.

Bulk transportation of hazardous materials that are toxic by inhalation, such as chlorine, is also on PHMSA's radar. While it is a very low-probability risk, it has extremely high safety consequences,

regardless of mode of transport. A similar low-likeness, high-toll risk is that of fire aboard an aircraft involving hazardous materials.

To address these potential risks, PHMSA has developed standards for loading and unloading bulk hazardous materials and for transporting flammable and combustible liquids and lithium batteries aboard aircraft. The agency also facilitated the development of advanced rail tank cars dedicated to bulk transport and is working to synchronize U.S. domestic regulations with international standards for air transport of hazardous materials.

PHMSA is increasing its safety focus beyond compliance with standards by promoting the development of a strong safety culture within the companies it regulates, and it is evaluating the use of management systems for safety, quality, and control-room risk mitigation due to human error. It is also targeting research into products, processes, and technologies that have the potential to provide safety benefits in hazardous materials and pipeline transport operations. At the same time, PHMSA is directing resources to expand overall research capacity and quality of data to better target and, thus, manage the most serious real and potential safety risks.

While the agency's primary focus is on incident prevention, it must also ensure that a strong and effective response capability is in place to reduce harmful outcomes. Toward that end, PHMSA has built in secondary containment requirements that limit the disbursement of hazardous materials in the case of primary packaging failure, improve leak-detection and shutoff control systems for gas and liquid pipelines, and advance the development of electronic shipping papers to improve access to and use of hazardous materials communication when an incident occurs. PHMSA has also worked to increase coordination, collaboration, and accountability among emergency responders, and to refine emergency response definitions and standards.

Need for Collaboration

The reduction of risks associated with pipeline and hazardous materials transportation is not solely the responsibility of PHMSA. While the agency serves in a leadership capacity, other federal agencies, state and local groups, international organizations, domestic businesses, and public citizens all have roles to play.

Federal, state, and local agencies provide essential support for PHMSA's programs in regard to

education, execution, and enforcement, while U.S. and international businesses hold primary responsibility for the safety of their own operations. The public's main role in hazardous materials and pipeline safety is awareness. People should be alert to potential risks and consequences and be cognizant of the extensive efforts being made within both the public and private sectors to ensure safe standards, practices, and accountability.

For its part, PHMSA is dedicated to gaining a better understanding of and target on safety risks by bolstering safety standards and enforcement, promoting a strong safety culture and systems, leveraging technology and research, optimizing effectiveness of collaborations, and expanding public education and awareness.

Planning, Programming, and Budgeting Systems

The use of Planning, Programming, and Budgeting Systems (PPBS) techniques in transit administration evolved during the 1960s and 1970s in the

United States. It was a means of organizing the essential processes that transportation authorities and policy makers needed to undertake in order to craft new systems and upgrade existing networks in a manner that would deliver maximum service benefits while keeping capital investments and operating costs under control.

Three Essential Steps

PPBS has been somewhat superseded by a range of other process-control methodologies in use by transportation administrators, although its key principles remain valid. The value of the PPBS process and the documents it generates can be useful whether the budget output represents the plans and programs of a public body or a private enterprise.

The first P—the plan—is the initial step in the technique. Data on goals, capabilities, material and personnel needs, and similar matters are gathered from the field operations staff. At the same time, directives and compliance requirements, along with strategic goals, are received from the oversight and funding authorities. Together, these criteria are synthesized into the plan. This is typically done at the very outset of a project and must then be repeated on an annual basis. Sometimes institutions or agencies also require three-year, five-year, and 10-year plans in order to build greater strategic vision, as well as to meet the more practical challenges of long-term budgeting, borrowing, and the effects these have on day-to-day operational capabilities, service levels, staffing, and related functions.

Once the plan is prepared, the key elements of the plan are input through various methods and practices to assemble the program, which is the second P. In this undertaking, it is recognized throughout the process that the output of this step will lead to the budget. Therefore, formats are structured with that goal in mind. The programming of the plan must be immediately recognizable, and its content readily accessible, to facilitate its use by both the internal and external financial administrative staff.

Programming typically features an overview, rosters of key decision makers and details on their staff complement and capabilities, an outline of timeline goals and milestones to enable monitoring of program progress once it is put into effect, information on internal and outside resources that will be called on to accomplish the plan at its different stages, and

any fiscal year carry-forwards or other fiduciary ramifications that will need to be discovered and explored in the budgeting segment of the process.

The B, or budgeting segment, is the presentation phase of the PPBS sequence, in which priority aspects of the plan, along with the major stages of the program, are translated into a codified, comprehensive statement of the expenditure and funding requirements for both long-term capital investment (e.g., right-of-way acquisition, infrastructure construction, and rolling stock purchase) and operational costs (e.g., workforce, contractor payments, utility and supply costs, and expense reimbursements).

The budget thus becomes the closest-to-reality component of this process. In its line-item translation, it serves as a dollar-and-cents statement of the strategic goals of the plan, as well as the toolkit of metrics encompassed in the programming. The budget provides the truest measure of the ways and means necessary to accomplish strategic goals and their everyday application, and the budget spells out the grants, loans, and ongoing funding streams that must be negotiated with targeted financial sources.

In this way, the budget of a public transportation entity also becomes the template for negotiation with the funding, administrative, regulatory oversight, and enforcement authorities of the enabling legislation.

Stages and Phases

Transit system planning is an extremely complex undertaking in which there is no single system applicable to all circumstances or markets. This has become increasingly clear especially in the context of the mandating of closer working relationships among federal, state, regional, and local transportation planners and a growing array of external constituents. These may include major industrial companies, service corporations, private or public real estate developers, energy and fuel providers, operators of the full range of transportation modes separate from that being planned, local homeowners associations, environmental protection groups, cultural preservation organizations, health care bodies, organized labor, media outlets, merchants associations, and both elected and appointed political bureaus and figures.

The integration of public-private partnership (P3) initiatives into planning has added yet

another layer of complexity, albeit one that often yields benefits to the planners. Beginning in the 1980s, the federal transportation leadership in the United States became more insistent on this front, impressing through a variety of documents, policies, and reports that P3s must be pursued to “capitalize on opportunities to integrate transit facilities into major new developments” by being “more aggressive in working with developers and local governments in growing parts of metropolitan areas,” as it was put in a U.S. Department of Transportation (DOT) recommendation issued in conjunction with the independent Transportation Research Board.

This trend was in no small part driven by harsh pressures on raising and maintaining funding levels for transportation projects; state and federal governments in the 1980s were generally faced with declining tax revenues as measured against rising funding mandates for non-transportation budgets, as well as historically high levels of inflation and its impact on borrowing rates. In some cases, planning authorities are legally mandated to pursue relationships with certain categories of constituents. In terms of the PPBS process, such constituents are partly transformed, in a sense, from external to internal considerations. The ramifications of various P3 activities must be incorporated into the planning, the programming, and the budgeting process.

Practical Matters

In the PPBS approach to strategic transportation system administration, the process must start with a comprehensive understanding of transit operations. This includes mastery of the methods and economic evaluation of scheduling vehicles and personnel, line capacity, the use of intelligent modeling in the analysis of design options and operational phases of a transit system, determining station locations and layouts, finding ways to increase operational efficiency and measure same, internal organizational structure, relations with labor and passenger populations, information technology advances, ticket tech, and fare dynamics.

Planners must also analyze and build in measures for meeting regulatory compliance standards and schedules, as well as the intricacies of varied sources of financing within and external to government bodies. In covering these criteria—essentially the practical building blocks of transit planning and

operations—many ratios and metrics are used to evaluate and balance such functions as improved service, fare revenues, transit speed, and customer satisfaction. These criteria, and the means to measure them, ideally will have been built into the system from the outset, through application of PPBS.

For example, one essential metric is level of service (LOS). This can be measured by a comparison of data on functions such as travel time, reliability, comfort, and the quite testable ability of a system to attract and keep passengers over time.

A core component of LOS is service quality, which itself is a compilation of the qualitatively examined aspects of service as experienced by the passengers. These include cleanliness, perceived safety of the system, aesthetics and ease of access to information, average seat availability, average wait time, riding comfort, convenience factors, fare prices and programs, and overall perception of value.

Modifications and Improvement

Although the PPBS approach continues to provide some fundamental ways and means of transportation system administration, the process has been faulted to some degree for a perceived lack of emphasis on quantitative and qualitative measurement and evaluation of outcomes. The types and scope of measurement and evaluation protocols that are more frequently applied tend to examine the execution, adjustment, and follow-through actions needed to provide a more holistic, closed-loop system that is thought to better support a strategic administrative approach. Thus, PPBS has in many cases been superseded by a PPBE approach, where the E is understood to mean “execution”—of the plan, of its components, and, particularly in complex and ongoing multiyear situations, of adjustments made to the original plan or plans.

The transition to PPBE was officially made during the 2002, 2003, and 2004 fiscal year periods, for example, by federal agencies including the National Aeronautics and Space Administration, the National Oceanic and Atmospheric Administration, and the Department of Defense (DOD). The DOD in its process noted the utility of PPBE as a means to “streamline connection between priorities and decisions,” and for its application as a way to improve “cost-benefit analysis of alternative programs” over the course of multiyear continuous budgetary regimes. PPBE in

sum is seen as a more reliable, flexible, and dynamic tool to provide feedback that compares and contrasts planned programs with real-world resource availability, actual performance, and changing conditions. Used appropriately, especially in high-level strategy planning and budgeting, PPBE can yield more transparency in links connecting expenditure, revenue, and related metrics.

Pneumatic Tube Transportation

Pneumatic tube transportation systems use compressed air to transport objects through a system of closed tubes. A basic system consists of two stations connected by a tube, with one station including an air compressor that is used either to create a vacuum to draw the object into the station or to create propulsive force by blowing air to push it away to the other station. Pneumatic tube systems have historically been used as a communication system and transport system in large buildings and as a method of delivering mail in cities.

Although various pneumatic tube train systems for human transportation have also been proposed, and a few actually built, all working systems have covered short distances and are no longer in operation. Different systems for human transport through evacuated tubes have also been proposed, but no working models have yet been built.

Transportation of Items

In the late 19th century, pneumatic transportation systems were commonly used in large department stores, mainly to transport money (hence, the term *cash carrier*) and small items or paperwork (for example, order slips) throughout the store; the items were placed in small capsules before being transported through the tubes. In terms of carrying cash, pneumatic tubes were a refinement of an earlier system that used cash placed inside wooden cylinders, which were rolled down sloping rails between the cash office and sales desks. The first patent for a department store pneumatic transportation system was granted in 1875, and the system was adopted in many large department stores by the 1880s.

The invention of the cash register reduced the need for the cash carrier systems, while self-service

In 1943, the passenger agents' room in Union Station in Chicago, Illinois, featured this pneumatic tube system, which rapidly delivered reservation diagrams for trains to Pullman porters.

stores reduced the need to transport order slips or small goods by this method. Yet, they are still used in some places (for example, J & R Electronics in New York City). Pneumatic tubes are also used for special applications, including transferring money and paperwork within casinos, where the extra security of a closed system is valued; and transporting medications, blood samples, and other small items through hospital systems, where both security and speed in handling physical items are valued.

The Central Research Library (now the Stephen A. Schwarzman Building) of the New York Public Library System used a pneumatic tube system to transport call slips from its opening in 1911 until 2012, facilitating rapid communication between the main reading room and the book stacks. Patrons filled out a paper call slip requesting a book or

journal, it was placed in a metal capsule, and the capsule was delivered pneumatically to employees working in the stacks, who would retrieve the requested items and place them in a dumbwaiter for delivery to the patron in the reading room.

Pneumatic tube systems were also used to deliver mail. Philadelphia was the first U.S. city to use this system, beginning in 1893, and Boston, New York, Brooklyn, Chicago, and St. Louis also built pneumatic mail-delivery systems. By 1915, the U.S. Postal Service estimated that, together, those cities had over 56 miles of underground pneumatic tubes used for mail delivery, with 27 miles in Manhattan, New York, alone.

The New York City system operated at 30 miles per hour (mph) and reached from Lower Manhattan to Harlem and across the Brooklyn Bridge to the main Brooklyn Post Office. Pneumatic mail service in the United States was suspended during World War I, then restored in Boston and New York, where it continued to operate into the 1950s. Several large European cities also developed pneumatic postal delivery systems, including London, Berlin, Paris, and Vienna. The pneumatic postal delivery system in Prague was completed in 1887 and remained in use until the 2002 floods put it out of operation; notably, the mail tubes were used during the Prague Uprising of 1945 to transport supplies.

Human Transportation

The concept of using pneumatic tubes to transport human beings has been used by several science fiction writers, from Jules Verne in *Paris in the 20th Century* (1863), which imagined pneumatic tubes undercrossing the Atlantic Ocean, to Neal Stephenson in *Downsiders* (1999), which imagines a colony of people called “downsiders” who live beneath the surface of New York City. It is noteworthy that Stephenson brings in the ideas of Alfred Ely Beach, an early publisher of *Scientific American*, who imagined a system of pneumatic tubes providing public transportation beneath the streets of New York City.

Beach actually began construction on his project, called the Beach Pneumatic Transit, constructing a tunnel under Broadway in Lower Manhattan for this purpose. A section of the railway opened to the public in 1870, operating a train over a one-block stretch of track as a demonstration project for the proposed system. However, the project was

delayed by official obstruction followed by a stock market crash, and it was never expanded.

In England, a pneumatic railway was built in 1864, designed by Thomas Webster Rammell and running for about 600 yards between two entrances to Crystal Palace Park in London. This short railway did open and carry passengers, but it was intended primarily as a demonstration project for a longer railway to run under the Thames River, which was never constructed.

Several research groups are working on the possibility of developing modern pneumatic railways through vacuum tubes, sometimes called “vacitrains.” However, although these systems are founded on the concept of transporting a capsule car carrying goods or people through a vacuum tube, the key purpose of the vacuum is to remove air resistance and thus enable faster travel with less expenditure of fuel.

The mechanical engineer Daryl Oster, founder and chief executive officer of ET3, is a contemporary advocate for the viability of vacitrains, which he calls evacuated tube travel (ETT) transportation systems. Oster’s idea is to use magnetic levitation (maglev) to transport car-sized capsules carrying six people or 800 pounds of cargo through evacuated tubes 5 feet in diameter.

The capsules would be started on their journey using electric motors and would coast through the tubes for most of the journey, regenerating most of the energy used as they slow down. If implemented, this would be more energy-efficient than any current system of vehicle transportation. However, this project remains at the level of theory, with no prototypes in operation to allow reasoned evaluation of the prospects for this type of transportation system.

Port Facilities

Ports are human-built facilities alongside which ships can be loaded or unloaded using cranes or, in the case of container ports, gantries. A port consists of quays and jetties where ships are tied, together with storage facilities for goods; larger ports also have transport connections to roads or rail systems. Some coastal ports also have access to waterways or canal systems on which goods can be transported inland by ship, boat, or barge.

Container ports are generally ocean or sea ports, although some very large ports are located along rivers. Examples include Rotterdam in the Netherlands (ranked 10th in the world for volume of goods throughput in 2011) and Tianjin on the River Haihe in China (ranked 11th). With the development of containerization have come larger ships, some of which can carry over 16,000 TEU (twenty-foot equivalent units). Consequently, larger cargo cranes and gantries have been developed to handle those ships.

History of Cargo Cranes

Prior to the introduction of containers to transport a wide range of bulk cargos, dry goods, and even food and perishable items in refrigerated containers, cargo was transported loosely in the holds of ships, on pallets, or in bales. It was a lengthy process to load and unload cargo and equipment in ports. Because the equipment, usually some type of crane, was often fairly basic, ships could spend

considerable periods of time being unloaded, and then be carefully reloaded before they could sail to their next port of call.

Historically, the first mention of cranes appears in writings from ancient Greece, although mechanisms to lift objects existed long before that. Leonardo da Vinci both described and designed cranes in the 15th century. Many of the cranes used by ports in the first half of the 20th century were little changed from those early designs, constructed in wood and using human-powered winches to lift cargo from ships. Early mechanized designs appeared in the mid-19th century that used steam power, for example.

In 1956, Malcolm McLean, a trucking company owner from North Carolina in the United States, operated the first ship converted to carry standard containers that could be easily transferred from truck to ship and vice versa. McLean had purchased a small shipping company in 1955, and his combination of road and shipping companies can be viewed as an early and small-scale example of what would become known as an intermodal transport network. In such a system, the same cargo is carried in a single container from point of origin to final destination without the need to remove it from that container.

The introduction of shipping containers in 1956 was a turning point for the transportation of cargo. It made it possible to load and off-load containers rapidly so that ships had to spend less time in port and, as a result, more perishable goods could be transported. Containers could be stacked inside the holds and on the decks of container ships, and could be transferred directly from ships to trucks or railcars within a container terminal. A revolution in the global transportation of goods commenced, with ships increasing in size and new ports being built in China, southeast Asia, and the Middle East, for example. Today, container ports are distributed across the globe, and many millions of containers are transported by sea each year.

Cargo Cranes and Gantries

In simple terms, cranes are machines that use a system of pulleys or levers to lift large weights. Cranes are generally either diesel-powered, with a diesel engine situated on the crane structure, or electric-powered, connected to a power source on the quay. Cranes can either be fixed in place on the

quayside, or they can be mobile and moved around the port to wherever required. They can be fitted with standard tires to run on roads or with wheels that are designed for use with railroad tracks. They can also use caterpillar tracks (continuous tracks like those used on tanks).

A cargo crane basically consists of a base, which can be any height or shape, from which a jib (boom or arm) extends out at an angle. In some cranes, the angle of the jib can be adjusted. Larger cranes can have a telescopic boom that can be extended so that cargo or containers can be loaded or off-loaded across the entire width of a ship.

From the jib is suspended a lifting mechanism such as a hook or crab (a grabbing tool), which is connected through a single cable. On this type of crane, the lifting mechanism is raised and lowered using a system of pulleys and connected to the cargo or load to be lifted. The boom can be rotated on a turntable, either at the bottom or top of the base, so that the cargo can be swung around and then lowered onto either the quayside or a waiting truck. However, a potential problem with this type of single-cable crane is that the container or cargo suspended at the end of the cable may start to swing or twist, particularly in windy conditions, and so may be difficult to control.

A standard gantry crane (or container-handling gantry crane) consists of one or more rectangular frames with a trolley (or cabin) suspended under the horizontal boom (a crosspiece or bridge) on rails that run underneath or on the side of that boom. The trolley is able to move laterally (left to right and vice versa) and is controlled by a driver sitting in a control cabin on the trolley. A moving hoist, known as a spreader, is suspended beneath the trolley and can be raised or lowered vertically on at least two cables, giving it greater stability than single-cable cranes.

In order to unload a container, the hoist is lowered and attached with locking screws or mechanisms at all four corners of the container, which is then lifted vertically until free of any obstruction. The trolley then moves laterally until it is over the truck, railcar, or container stack. Some gantry cranes are mobile—either rubber-tired gantry cranes (RTGs) or rail-mounted gantry cranes (RMGs)—and can move around with the container suspended underneath until it reaches its required destination.

A gantry crane designed to load and unload ships (ship-to-shore gantry crane) can be moved along the quayside to come alongside a ship, or the ship can tie up next to the crane. This type of gantry crane differs from the standard version in that it has an extended crosspiece that extends out beyond the edge of the quay, allowing the trolley to move above the ship and unload containers across its full width.

Container ships have grown in size since the gantry-crane concept was first developed, when ships and cranes were categorized based on a measure originally established for the size of ships able to travel through the Panama Canal. In reference to the canal, Panamax cranes can unload ships that are between 12 and 13 containers wide, while Post-Panamax can extend to roughly 18 containers wide. The Super-Panamax has a range up to 22 containers wide.

As ship sizes have grown, so have the size and lifting capacity of cranes. Some modern cranes can lift up to four 20-foot-long or two 40-foot-long containers simultaneously, and some can lift weights to 120 tons. There are also cranes with a jib radius (the distance the crane's arm or gantry boom can reach) of up to 120 feet (36 meters), enabling them to lift containers from the widest Super-Panamax containerships.

With all cranes, it is critical to know the weight of the container to be moved. Cranes with long jib arms or telescopic jibs may overbalance if the weight is excessive. Similarly, the structural integrity of a gantry crane may be compromised if the weight is too great, particularly if the trolley is at the farthest limits of the crosspiece, causing its rectangular frame to bend or break.

Containers are generally measured in terms of their size and volume, such as 20-foot equivalent units (TEUs) and 40-foot equivalent units (FEUs), and it is very important to know the actual weight of the containers to ensure that they can be lifted safely.

Gantry cranes are an essential tool in ports to ensure the efficient loading and unloading of cargo and the movement of containers around the port area. However, it is unclear how much larger it is possible to build cranes, particularly for existing container ports that might not have sufficient space to accommodate larger cranes. Developments in electronic tracking of containers, to both map their location and plan the most efficient routes for

cranes to move through the port area, may be the next stage in ensuring the rapid throughput of containers that is so vital for ports to be competitive in the global arena.

Port Inspections

Port inspections fall into two categories: (1) those directed at the port area and cargo or containers, executed to ensure their safety and to search for smuggled goods such as drugs, weapons, or individuals; and (2) those directed at ships using a port. In the former case, for the majority of ports, inspections are carried out under international rules set out and administered by the International Maritime

Organization (IMO), while additional security measures are in place for container ports that trade with the United States.

In the latter case, those inspections examine the ship to ensure that it is seaworthy and safe to travel to its next destination, that it is in compliance with a range of international conventions and regional measures, that crew conditions are satisfactory, and that it does not pose a risk to the environment from pollution. A number of regional bodies have been established around the globe to conduct those inspections and to ensure a safe and secure maritime transport industry.

Securing the Port Environment

Following the attacks on the United States on September 11, 2001, there was a growing perception that seaports, and particularly container ports or those receiving petroleum and gas products, could be a target for terrorist activities. As a result, in 2004, a new chapter was added to the 1974 International Convention on the Safety of Life at Sea (SOLAS), one of the conventions administered by the IMO, the agency of the United Nations responsible for the safety and security of shipping and the prevention of marine pollution from ships, for example. That new chapter is SOLAS Chapter XI-2, which sets out special measures to enhance maritime security. In addition, the IMO introduced the International Ship and Port Facility Security Code (ISPS), a framework for governments, ships, and ports to work together to detect and deter threats to maritime transport.

The ISPS Code comes in two parts. Part A, which is mandatory for all countries that are signatories to the SOLAS Convention, requires those signatory states to ensure the security of ships and ports through the use of risk assessments, and also requires both ships and ports to appoint a security officer and to develop a Security Plan. Part B provides guidance on how to implement Part A. Signatory states are involved in setting security levels on ships and in ports if a threat is identified, and in communicating those security measures as necessary.

Ports that fall under the ISPS Code are required to have a security assessment conducted by a recognized security agency. This assessment should cover areas including but not limited to the following: perimeter security measures from land and sea to limit access to the port to only those

authorized to be there and to detect break-ins; methods to ensure that only authorized individuals (for example, employees of the port itself, including dock workers and administrative staff, and nonport employees, such as truck drivers and customers officials) can access the port area; detection systems for drugs and weapons or explosives; identification of areas requiring specific security measures, including connections to utilities (electricity, gas, water supply), infrastructure including equipment, secure storage areas, and bonded warehouses (where items on which excise duty must be paid are stored); and securing any areas where hazardous materials are stored.

Once an assessment has been conducted, the port security officer develops and regularly updates a security plan, and ensures that all employees are aware of what they need to do in the event of it being activated. It includes which measures are to be taken to ensure that cargo, containers, essential equipment, port buildings, and infrastructure are not tampered with in any way.

In addition to the ISPS Code, joint work was undertaken between the International Labor Organization (ILO) and the IMO to develop an ILO/IMO Code of Practice on Security in Ports. Although not legally binding, this code provides guidance to all parties involved in port security, including governments, port employees, and workers, to reduce the risk to ports from any potential security threat. It also provides guidance on how to carry out a port security assessment and develop a port security plan.

U.S. Container Security Initiative

In addition to the measures put in place by the IMO internationally, the United States introduced a Container Security Initiative (CSI) in 2002. That initiative aimed to develop a system of prescreening of shipping containers destined for the United States while still in a foreign port. Under this system, U.S. Customs and Border Protection (CBP) works with foreign customs services to inspect high-risk containers and, at the time of this writing, 58 foreign ports were participating in the CSI, covering 85 percent of all container traffic bound for the United States.

The three main elements of the CSI are identifying high-risk containers that pose a potential risk from terrorists, screening them before they depart

for the United States, and using technology to conduct that screening without causing any delays in the transport of the cargo.

Identification of high-risk containers is done using the advanced analysis of information contained in cargo manifests or bills of lading, which must be submitted to the CBP at least 24 hours before the container is loaded on a ship destined for the United States. The information provided is screened using an Automated Targeting System, which identifies shipping containers that pose the highest risk based on their contents and targets them for inspection. A benefit of this system is that containers with no or very low risk, particularly those where some form of electronic or physical seal is in place to prevent the contents from being tampered with, can be transported much more rapidly.

Once a container has been identified as being high risk, it is inspected in port (or potentially even before it arrives in the port, if information is provided at an early stage in its transportation). In many ports, particularly those with limited access to technology, containers are inspected manually. This can involve all of its contents being removed and examined by hand, and may even include manufactured goods being disassembled to check that nothing is being smuggled within them. This also may result in considerable delays, particularly if the container is filled with different types of goods from a number of different sources, and where there is extensive paperwork associated with its contents. In addition, canine teams may be used to search for drugs or other substances, or stowaways hidden within a container.

In order to speed up the process in CSI ports, a number of nonintrusive methods are available to screen a container, including X-ray or gamma-ray scanners to generate an image of the contents and identify whether any additional searches are needed. Radiation detection devices also can be used. This technology means that far fewer containers will need manual inspection, and so ships can be loaded more quickly, speeding up the transport of goods from CSI ports to the U.S. mainland.

In order to further assist with the security of containers, geographic information system tracking can be used to geographically locate containers and provide an up-to-date location at any point in the container's journey. Security seals can be added to containers after they have been cleared

by inspection; these are designed to ensure that the container and its contents remain untouched until they arrive at their final destination.

Inspections of Ships in Port

The second type of inspections conducted in ports are intended to ensure that ships entering a port are in compliance with international conventions and any regional measures (for example, European Union directives) or national or state-level legislation. These inspections are carried out under a system of Port State Control, where foreign-flagged ships (sailing under the flag of a country different from that of the port) can be inspected to ensure that they meet required standards and that they, and their crews, are safe to sail on to their next destination.

Ship inspections are conducted under a network of regional Memoranda of Understanding (MOU) on Port State Control regimes around the globe. Nine MOUs were established globally between 1982 and 2005, and they cover all the world's oceans. The first of these was the Paris MOU, which covers Europe and the North Atlantic, and the most recent is the Riyadh MOU, which covers the Arabian Gulf region.

While the United States is not a signatory to any of the MOU regimes, it is an observer to the Black Sea and Tokyo MOUs, and port state control activities and inspections are conducted by the U.S. Coast Guard. U.S. inspections cover compliance with environmental, safety, and security measures, as well as the adequate identification of ships' crews and tracking of ships at sea.

Each MOU regime works with the IMO to ensure that ships entering member-state ports are in compliance with a range of international conventions, and also any relevant regional agreements, treaties, or regulations. For example, European Union member states that are signatories to one or more of the Black Sea, Paris, or Mediterranean MOUs may also be required to ensure that ships adhere to the requirements of any relevant EU directives, wherever an agreement has been reached to include such measures in the ship inspections.

Inspection Procedures

Inspections of ships in ports are conducted by Port State Control Officers (PSCOs) once a ship has been identified as needing inspection. Inspection

U.S. Customs and Border Protection (CBP) officers board a ship to begin a port inspection in May 2004. CBP works with foreign customs services in 58 foreign ports to prescreen high-risk containers, a system that covers 85 percent of all container traffic bound for the United States.

triggers include a port being informed that deficiencies have been previously identified on the ship, that a pilot bringing a ship into port has identified problems relating to safe navigation of the ship, that the ship is carrying dangerous or polluting goods on board, that it has failed to supply the port with full details, or the ship has not visited a port in an MOU member state for over a year. It can also occur if the documents held by a ship are not from a recognized authority.

An initial inspection of a ship includes checks on the overall condition of the ship and its hygiene. The PSCO checks for areas of corrosion and cracks on the vessels hull, for example, or whether

regular safety drills have been carried out. The initial inspection covers the bridge, accommodations, galley, decks, cargo holds, and engine room to make sure they meet acceptable standards, that any problems identified during a previous inspection have been corrected, and that all the relevant standards are being met. It also checks that all the relevant documentation is available and up-to-date. This covers areas including safety certificates for radio or safety equipment, certificates relating to SOLAS, and medical certificates for the ship's crew.

If there are any deficiencies or problems identified during the initial inspection, or if all the required certificates and documentation are not available to the PSCO, a more detailed inspection will be conducted. That inspection will cover not only those areas where a deficiency has been identified but also a random selection from a list of 14 risk areas on board. Those risk areas include the structural condition of the ship, that it is water- and weather-tight, that all the emergency systems are in working order, that radio communications are working correctly, and that life-saving appliances, such as lifeboats, life rafts and life belts, are well maintained and accessible.

An expanded inspection may also be conducted if the PSCO considers this appropriate, and all 14 risk areas are included in this inspection. If a ship fails a port inspection, it may be permitted to sail to another port if the deficiencies are minor or if repairs cannot be carried out in the current port. However, for major deficiencies, the ship may be detained in port and prevented from leaving until all work to fix identified problems has been completed.

International Conventions Covered by MOU

There are a number of international conventions and their protocols (amendments at a later date) covered by MOU port inspections, and against which ships can be inspected for compliance. The Paris MOU inspects against 10 conventions, nine of which are administered by the IMO and one of which is a convention of the ILO. This is the Merchant Shipping (Minimum Standards) Convention of 1976 and its Protocol of 1996, which covers areas including the setting of a minimum age for seafarers, requirements for crew accommodation, and measures relating to the prevention of accidents.

Of the remaining nine conventions for inspection under the Paris MOU, one is the SOLAS convention discussed previously, which covers safety

aspects onboard ship, including fire safety, life-saving equipment, carriage of cargoes or dangerous goods, and any measures to ensure the safety of a ship both at sea and in port.

Another convention with measures directly impacting both ships and ports is the International Convention on the Prevention of Pollution from Ships 1973, and its Protocol of 1978. This sets out requirements for ships regarding where and how much of different categories of wastes can be discharged at sea. It covers oil, noxious liquids, hazardous substances in packaged form, sewage, garbage, and air pollution from ships. It also includes measures requiring ports to provide reception facilities for certain types of waste. This convention aims to reduce pollution entering the marine environment and includes measures relating to ship inspections in ports.

Other examples of IMO conventions covered within inspections include the International Convention on Load Lines 1966 and its Protocol of 1988, and the International Convention on Standards of Training, Certification and Watch-keeping for Seafarers (STCW) 1978. Load lines were introduced as a measure to prevent ships from being overloaded in port, using a system known as reserve buoyancy that identifies how low a vessel can ride when fully loaded and remain watertight, depending on the region and water type (for example, freshwater or seawater, summer or winter) where it sails. The STCW covers minimum standards for various members of a ship's crew and also for different types of ships. PSC inspections are required to check that certificates for all crew members are up-to-date, and that they have received the appropriate training for their rank and the type of ship they are working on.

Ensuring compliance with the various conventions, as well as any regional agreements, is the responsibility of the specific MOU regime. Those regimes also set out a minimum number of ships to be inspected in its ports annually, based on a percentage of the number visiting. Ships visiting ports in the Tokyo MOU region are far more likely to be inspected because it has a target rate of 80 percent of both foreign-flagged and MOU-member-flagged ships to be inspected annually. Under the Paris MOU regime, the target is 25 percent, while the Indian Ocean and Riyadh MOUs set a target of 10 percent; the remainder have targets between 10

percent and 20 percent. In other words, the number of inspections carried out in the Asia-Pacific region is much higher than anywhere else in the world.

Privately Owned Vehicles

Throughout the developed world, automobile trips account for about 70 percent of all trips not made on foot; in the United States, they are responsible for nearly 90 percent, as well as virtually all nonwork travel (more than half of public transit use being for work/commuting purposes). After mortgage or rent, transportation is the largest expense in the average American household, even exceeding education, despite the ballooning costs of tuition. Even today, when American manufacturing has been in steady decline for many years, car manufacturing and services account for 4.5 percent of U.S. employment.

The United States has one of the highest rates of automobile ownership in the world. According to the World Bank, which measures motor vehicle ownership in several ways, the United States has the third-highest ratio of motor vehicle ownership per thousand people (a statistic that includes buses and commercial and freight motor road vehicles in addition to automobiles, SUVs, vans, and pickup trucks), exceeded only by the small wealthy nations of San Marino and Monaco.

This rating is inflated somewhat by the size of the commercial trucking industry in the United States, but the World Bank also measures private car ownership, and the United States ranks among the highest, with 423 cars per 1,000 people in 2010 (down from 450 in 2008). While historically the United States has ranked among the countries highest in car ownership, in recent years more European countries have begun to overtake it.

The United States is one of the largest countries in the world by area, which is a factor both in its

unusually large fleet of freight vehicles and its relative lack of comprehensive public transportation for so much of the population. (The cities with the smallest percentages of car-owning households are predominantly northeastern urban centers with enough population density to make driving less practical than public transit—the New York metropolitan area accounts for the three smallest, followed by Washington, D.C., and Hartford.) Given its large population and its large number of vehicles per capita, it is no surprise that the United States has the largest fleet of passenger vehicles in the world, and has for many years. Historically, it has also led the world in annual automobile sales, though this changed in 2011.

That said, in the wake of the 2008 financial crisis and findings of the 2010 U.S. Census, many suggested that "peak driving" had been reached, and after steadily climbing for decades (even in the face of active attempts to reduce car dependence), car ownership and use would enter a decline. A report from Transportation Research Institute researcher Michael Sivak found that even prior to the 2008 economic crisis, the ratios of vehicles per person, per licensed driver, and per household had hit their maximums, and had been declining since, just as the absolute number of vehicles had begun declining after the recession.

Not all of the factors are clear, though Sivak notes that the number of telecommuters increased by a third from 2000 to 2013, and the number of teenagers obtaining their driver's license at later ages had increased. Declines have also been seen in other previous leaders in driving, including France and the United Kingdom, both early adopters of car culture.

However, even as car ownership and driving decrease in the United States, they are increasing significantly worldwide, as developing nations grow their middle classes. In 2011, China overtook the United States in automobile sales, and 2012 and 2013 each set new highs in global automobile production. Because the transportation infrastructure has developed more quickly in developing nations due to improvements in technology, efficiency, and the industries supporting such infrastructure, car ownership has been adopted faster; and developing nations typically have a higher rate of car ownership than the developed nations, including the United States, had achieved at equivalent levels of income

or gross domestic product. Of course, massive car ownership expansion was also a major factor in China's 2010 11-day traffic jam.

National Household Travel Survey

The most recent National Household Travel Survey (NHTS) was administered in 2009, too long ago to reflect or address these trends. The NHTS is administered by the Federal Highway Administration for the U.S. Department of Transportation, at irregular intervals, having previously been administered in 2001 and preceded by five similar surveys from 1969 to 1995. Like the census, the NHTS is a comprehensive survey of the United States, but focused on travel: every trip made in a 24-hour period by each surveyed household, whether walking to the mailbox or driving to a grandmother's house.

One of the only other countries that tracks as many travel statistics as the United States is the United Kingdom (UK), which has found that car usage peaked in the 2000s and that most statistics reflecting drivership and car usage have either plateaued or declined in the 2010s. Some of the decline in car usage is simply a fact of changing demographics.

The first generation for whom driving was default behavior and car ownership an assumed eventuality has now retired; the number of retired drivers continues to rise, and the baby boom generation's unusually large size has increased the share of retirees in the population. Thus, even preserving the status quo of behavior patterns—upon retirement, many drive less often because they are no longer driving to work—would result in a decline of vehicle miles per licensed driver.

Another trend seen both in the United States and in Britain, as well as in France, Norway, South Korea, and Germany, is young people waiting longer to get their licenses than they had in the past. In 2010, only 28 percent of 16 year olds had licenses, compared to 46 percent in 1983; 46 percent of 17 year-olds, down from 69 percent; 61 percent of 18 year olds, down from 80 percent; 70 percent of 19 year olds, down from 87 percent; and 81 percent of 20 to 24 year olds, down from 92 percent.

Americans under 35 in general have proven to be far less interested in driving than previous generations, and several studies have suggested various reasons to explain this, all of which may

Private cars, taxicabs, and a bus vie for position in heavy traffic near a railway station in Xiamen, Fujian Province, China. China has surpassed the United States in automobile sales and is experiencing rapid growth in private automobile ownership.

be contributing factors: young people are more socially and environmentally conscious, which makes them less enthusiastic about driving; they are enthusiastic supporters of public transportation, which meets many of their travel needs (according to a Frontier Group study, public transportation usage doubled from 2001 to 2009 among Americans aged 16 to 34 in households with incomes over \$70,000); they are less likely to have children, freeing them from many of the errands that cars make easier; in recent years, larger numbers of them have moved back home with their parents, who may perform many of the errands a car requires; and they are the generation most at home online, which some say has replaced

a portion of the car trips other drivers perform for social or recreational purposes.

Privatization of Public Transit

Privatization is the transfer of publicly owned assets or publicly operated services to private ownership or operation. Privatization of public transit systems takes many forms. Moves to privatize public transit are usually motivated by a combination of cost pressures on governments and a desire for improved transit services. At the same time, though, the operation of public transit requires legal and regulatory powers that only governments can provide. There is also political pressure for transit operators to provide services in circumstances that do not generate commercial returns. Not surprisingly, therefore, privatization is almost always a controversial and contested process.

Historical Context

Prolonged worldwide economic stagnation in the 1970s and 1980s diminished the capacity of

governments in modern industrialized countries to fund many projects. Privatization became a significant part of a reform agenda to shift control and ownership of productive resources to private-sector entities. At the same time, those activities left in state control and responsibility were subject to marketization reforms. These involved the competitive supply of services by the private sector, on the one hand, and the expectation that government enterprises would mimic private corporations, at least as far as management practices were concerned, on the other.

The United Kingdom became a worldwide leader in privatization following the election of Margaret Thatcher's Conservative Party government in 1979. Privatization became widespread shortly afterward across Europe and in the United States, especially, under the leadership of President Ronald Reagan (1980–88). The collapse of communism in eastern Europe in the late 1980s and early 1990s saw the onset of privatization measures in that region. This was part of the widespread dismantling of systems of state-planned and -controlled development, as well as the sell-off of state-owned enterprises (SOEs).

Concerted privatization programs in developing countries also date from the 1980s and 1990s. The initial impetus for the sell-off of SOEs came from rising public indebtedness in a number of Latin American, east Asian, and sub-Saharan African nations in the mid- and late 1980s. In these regions, privatization was a central part of the International Monetary Fund's (IMF) structural adjustment programs for developing nations in need of assistance.

Types of Privatization

It is possible to identify three general types of privatization. The most common form is the sale of SOEs into private ownership. However, there are considerable difficulties when it comes to the outright sale of public transit systems. This is because a public transit system is usually a bundle of integrated assets acquired as the system developed over time, usually in the hands of a government-owned utility. In the case of a rail or metro service, for example, this bundle of assets might include the rolling stock; the rail and signaling assets; stations and associated amenities; fare-collection systems; operational, administrative, and management teams; integrated retail

spaces; parking spaces; unused land and air spaces that might be valued for commercial property development; the property rights that guarantee passage across a city; and other infrastructure assets, such as information technology (IT) cabling or water pipes, which often co-use a rail passageway.

Some of these assets can be dismantled quite easily to be sold to commercial operators or developers. For example, car parks and idle land around railway stations could be sold to a parking lot operator. Even a fare-collection service could be run by an external company, in a similar way to how large retailers outsource their credit and cash register systems to specialist financial-services firms.

Unbundling other assets is much more difficult. One strength of government-owned utilities is the way they enable public transit services to be operated in ways that exploit their natural monopoly status for public benefit. A natural monopoly occurs when it makes no sense for a product or service to be supplied by more than a single provider. It would be inefficient, for example, to have rival metro systems attempting to provide blanket coverage across a single metropolitan region. One well-functioning metro system is quite enough.

Privatizing natural monopolies, then, comes up against the problem of how to introduce competition and develop markets without sacrificing the benefits that flow from having a single large, integrated public provider—whether it be water, energy, telecommunications, school education, or public transport. Can a group of rail companies, for example, compete for commuters on a single rail surface without the loss of coordinated timetables and integrated services that are intrinsic to a well-functioning rail or metro system? Can railway stations be separately owned and still genuinely compete for users? Can signaling services be based on the same private-sector market disciplines that apply to, say, the supply of groceries or clothes?

Privatization also refers to a shift in responsibility for the provision of basic and community services from the public sector to commercial, for-profit enterprises. A common expectation that developed around the world during the 20th century was that the function of a nation is to organize the provision of basic services for its citizens. Many of these services fall into a category called public goods, which are goods or services that are created through universal provision. Public transit

services came to be seen as a public good because the personal and private provision of, say, a light-rail service today makes no sense. A viable suburban light-rail service can only come into existence as a public good, just as an apple or a haircut can only ever belong to the private-consumption category.

Yet, many governments have privatized the provision of public goods, including transit systems, but they have done so in contractual ways that mandate conditions that more or less correspond to public-goods expectations. Sometimes this type of privatization is accompanied by a subsidy or concession to ensure access by some users on a noncommercial basis, typically based on equity or need criteria.

At the edges of the public transit system, there are also many services that are readily contracted out to private providers. These include simple things such as retail spaces on passenger concourses, cleaning and maintenance contracts, payroll and other administrative services, and so on.

Privatization also refers to a shift in regulatory roles away from centralized determination by governments and government agencies. Examples of the shift away from state-led regulatory systems include the following: the adoption of regulatory standards developed by supra-national agencies, such as the International Organization for Standards (ISO); industry-based regulatory bodies, sometimes called self-regulation systems; shifts away from centralized, state-administered labor regulations to work arrangements based on employer–employee contractual relations; and the replacement of authorities with responsibility for the conduct of social and sporting events with bodies drawn from the voluntary and community sectors.

The shifts in regulatory responsibility away from the state, or the abandonment of regulations altogether, are often described by reformers as either deregulation or market liberalization policies.

Unbundling

Unbundling confronts the problem of the privatization of public services when these have been sourced from integrated public utilities. As mentioned, there is a wide range of valuable assets and commercial rights that utilities are able to assemble. Dismantling public utilities, including those involved in transit services, has created two

major problems. The first is the problem of how to introduce market competition in a sector dominated by natural monopolies. The second is how to maintain the benefits of an integrated operational system when the parts of that system are sold off or contracted out to private, for-profit owners and operators.

Solving these problems involves the introduction of two different types of marketization processes. One is competition within the market. In the case of public transit systems, such as the UK interurban rail system, competition for the market involves bidding between rival rail operators for designated rail services for limited periods, but also the opportunity for the introduction of new services that might attract additional patronage and, therefore, money-making opportunities.

Of course, both competition and innovation require the use of common railway thoroughfares. Hence, genuine market competition is compromised by the need to maintain orderly timetables and uncongested rail corridors. A role for governments as strong market regulators and contracts/concessions negotiators becomes essential, then, as ingredients to facilitate competition among transit operators.

The second solution is competition for the market. In this case, governments sell monopoly rights to those parts of the transit system for which it makes no sense to have competing providers (for example, for stations, signals, and tracks). These rights sales are seen to have market discipline because they are based on competitive bidding, and because they require scrutiny by a regulator with regard to quality of services, pricing, and rates of return on capital. In this sense, the private producer is seen to be behaving as if it were in a competitive market situation.

Effects of Privatization

A successful privatization program would see governments relieved of the burden to supply expensive infrastructure capital, and consumers enjoying better transit services at cheaper rates. Unfortunately, it is difficult to find examples where governments and consumers agree that the privatization process has been an unmitigated success. Inevitably, because privatization introduces conflict between the desire of a private firm to maximize revenue and profits, and the desire of

passengers to enjoy ever-improving services at lower costs, there will never be full agreement on the benefits of privatization.

Moreover, just as state-run utilities often fail to achieve their ideal of a universal provision of quality public services, so, too, do privatized transit systems suffer from failure on their terms, a situation called “market failure.” Market failure can be very dramatic; for example, when a major transit operator fails financially, ceasing operations and thereby leaving vast tracts of an urban area without commuter-train services, the government has no easy way of introducing an alternate supplier.

Although there is widespread evidence that the privatization of public transit systems has led to more efficient service provision and reduced cost pressures on governments, the commercial viability of privatization often comes at the expense of the end user, who may have to endure crowded commuter services, rising fares, and the loss of conveniences such as transit that still runs late at night when customer patronage levels are low.

Public Participation in Transportation Planning

Public participation includes stakeholders in making and implementing public policies and programs of government agencies, political leaders, or nonprofit organizations. It has become a fundamental feature of governance in a wide range of public issues.

Public participation plays an important role in a variety of transportation-related activities, including planning, formal policy making, program and service design, and evaluation. Notably, the Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991 imposed new requirements for public involvement in the planning process in the United States. Public participation can be designed in a variety of ways, guided by a few key questions about its purpose, the stakeholders, and the evaluation measures. Other common terms for public participation include public engagement, citizen participation, civic engagement, collaborative governance, stakeholder involvement, and inclusion and representation in democracy.

Public participation in transportation planning takes a range of forms, including simply informing stakeholders of decisions that are being made, soliciting and using their input on programs or policies under consideration, or collaborating with them to identify and address problems. Transportation policy stakeholders are those with a stake in the decision, which may include the general public and/or groups with specific interests, because of their geographic location, transportation needs, or related concerns.

There is no formula for doing public participation well. Like transportation services or infrastructure, public participation needs to be designed for its particular context. Regardless of the specific strategy, policy makers and planners must consider several critical factors in designing and managing successful public participation: clarifying what parts of the decision are open for discussion and change, ensuring public trust in the process, working with expert and other perspectives, and being accessible to all stakeholders.

Although public participation requires resources such as skill, time, and money, it generates numerous advantages. Citizen participants contribute

new information, different ways of seeing an issue, and motivation to address problems. Public participation can also result in more equitable distribution of limited public resources. The public tends to have more informed involvement and a higher level of interest when given opportunities to identify priorities, shape decision-making parameters, or influence policy outcomes.

Participatory decision making generates better buy-in and can limit delays, mistakes, and lawsuits during project and policy implementation. Stakeholders are more likely to accept a decision reached in a participatory manner, even when it is not their individually preferred outcome, because they believe it was produced in a fair manner. In fact, inclusive participation can create relationships of trust, knowledge of and interest in transportation issues, and improved communication among parties that are resources for policy implementation and for addressing new or different problems.

Designing Public Participation

There is no one-size-fits-all, ideal approach to public participation but rather myriad techniques and frameworks. Choosing among these approaches is both challenging and consequential. The forms of public participation influence the quality of policy outcomes and affect the capacity to address current and future issues. Guided by a few key questions about its purpose, the role of stakeholders, the methods for organizing the effort, and the evaluation measures, it can be done well.

Transportation planners should begin participation efforts by considering the purposes of the public engagement effort, including what is at stake and what the desired outcomes are. Deciding what is at stake includes evaluating which parts of a decision are available for stakeholder participation. For example, some aspects of transportation planning are dictated by legal requirements, best left to engineers or other experts in a particular technical field, or unable to be decided by a single jurisdiction and its constituents.

In terms of desired outcomes, a particular effort may involve more than one purpose, such as meeting regulatory requirements for participation, being sure that stakeholders are informed about a proposed action, exploring the nature of an emerging problem, improving the quality of a proposed project or policy through stakeholder

feedback, generating ideas for a new initiative, or building relationships for implementation or future problem-solving.

Once they have identified desired outcomes and the appropriate scope of the public's participation, policy makers decide which techniques to use and how to communicate with stakeholders about what to expect and how to participate. An accessible and popular tool to help with this is the Spectrum of Public Participation created by the International Association for Public Participation (IAP2). The Spectrum identifies differing levels of public engagement depending upon the goals, resources, impact, and time frame for the decision. It clarifies that no one approach is better than another, but that goals, communication with stakeholders, and techniques must be aligned. Being very clear about the purpose and scope of public participation helps build trust and legitimacy for the participation process and its outcomes.

Existing Approaches to Public Participation

There are many methods for involving the public in transportation planning, from a public hearing before the elected or appointed body making a decision to more inclusive approaches in which stakeholders are involved in identifying problems and coproducing solutions. In the past decade, transportation agencies around the world have involved the public in a number of ways:

Advisory boards. Advisory boards are comprised of a group of stakeholders recruited to provide guidance on a policy area or project. Members may be selected by elected officials, commissions, public administrators, and project managers. They may be intended to represent the public at large, to bring a particular perspective (for example, an advisory committee on disabled transit riders), or to incorporate a range of stakeholder groups. Advisory groups may meet regularly, as needed, or for a limited term to address a particular question. They do not generally have policy-making authority, and their influence on policy agendas and outcomes is mixed.

Project review teams. These teams help transportation professionals to evaluate possible transportation projects. They may rank projects from a pool of proposals or simply share comments and raise

questions for transportation professionals to incorporate into their reviews.

Collaborative performance measurement. Collaborative performance measurement brings together service providers with stakeholders to evaluate service or project performance. It can be used to evaluate performance problems and to identify and address situations where different parties have divergent goals and expectations for a service.

Focus groups and workshops. Focus groups and workshops help professional staff or political leaders to gain additional perspectives on a problem through consultation with interested stakeholders or with members of the general public. Participants may be given a set of questions or issues to discuss or be invited to comment on a policy. The consultations can be designed for a variety of purposes, such as gaining information about issues of greatest concern to constituents, involving a program's users in its performance evaluation, or improving a project so that it is more politically feasible or more responsive to client needs.

Deliberative polls. Deliberative polls are a trademarked method for identifying the questions that the general public would have about a policy issue if they became better informed and discussed them in depth with people with differing viewpoints. These polls can lead to better communication strategies about transportation policies. Participants are randomly selected, prepared with a briefing packet, and invited to attend a deliberative forum in which small, facilitated groups discuss the issue and decide together which questions about the policy they would like to pose to experts and decision makers. Organizers later relay their questions to the media, policy makers, or experts.

Planning charrettes. Planning charrettes are collaborative design exercises that allow stakeholders to directly experience, manipulate, and play with design components through games, simulations, maps, field trips, or other objects or experiences. They typically incorporate a variety of media, such as 3-D models, photography, and rendered landscape images. The models can be shaped to communicate which parts of a project are fixed (for example, lane width) and which are flexible. Planning charrettes

can help the public to understand transportation options and communicate their questions and suggestions to engineers and planners. Using mixed media may be associated with greater public satisfaction with the outcomes.

Structured public involvement. Structured public involvement (SPI) involves the public in every decision phase, from defining the nature of the transportation problem to creating the scope for the policy to setting design goals and refining the options together. Recommended as a best practice for involving the public in design decisions, it occurs through focused explorations and strategizing about separate pieces of the policy. Piece by piece, participants suggest ideas and make modifications concerning each piece until there is general agreement, and then integrate it with other pieces of the policy. When convening these processes, transportation professionals must be responsive to multiple perspectives, help nonexpert participants understand the technical aspects of the policies, be competent facilitators, and be willing to cede some of their decision-making power.

Interactive optimization tools. Interactive optimization tools involve the public in manipulating a fixed set of resources to choose among a menu of policy options. In some designs, users can move back and forth between setting performance criteria (for example, persons moved per hour) or resource parameters (for example, a total budget) and the menu of projects, so that they can see the interplay between them. Frequently they use an online platform.

Participatory action research. Participatory action research involves researchers working with interested parties to perform research driven by their questions and concerns. Activities include gathering and analyzing data, identifying problems to address, or generating and evaluating policies. Developing these community-led initiatives requires technical assistance. Some researchers provide pro bono support, or sometimes transportation agencies provide consulting support. Generally, institutional actors must have buy-in in order for the resident-driven contributions to be taken seriously.

Geographic analysis of public comments. This analysis uses geographic information systems (GIS) to

identify geographically based needs for additional outreach about transportation decisions and to identify geographically specific patterns of feedback about projects.

Key Challenges

Several challenges commonly arise in designing and managing successful public involvement in transportation policy making: the legitimacy of and trust in the engagement process, incorporating expert and other perspectives in technically complex transportation decisions, and engaging diverse stakeholders.

Trust and Legitimacy Issues in Engagement

One complaint commonly raised by the public about engagement processes is that their involvement does not seem to influence decisions. This causes resentment when stakeholders are invited to participate, yet there is very little that can be changed in the policies or projects that have already been put together. Sometimes conflict occurs when sponsors have not communicated what the participation is for, and participants arrive with different expectations, for example, if a public agency is simply informing the public of a decision and the public arrives wanting to change it.

If their different expectations are not ironed out, public processes can easily become mired in conflicts about their legitimacy, sometimes leading to accusations that they are perfunctory or manipulative. The IAP2 Spectrum suggests good ways to communicate with the public about the engagement's purpose, for example, "We will keep you informed" versus "We will implement what you decide."

Timing is an important part of accomplishing and communicating the goals for engagement. Consulting with stakeholders early in policy development allows policy makers to better shape the scope, priorities, or performance measures of the work. A two-way information exchange is most needed in the planning and design phases, so that stakeholders can weigh in on the most suitable goals and design of a project. A one-way process is more appropriate for the construction stage of a project, when the focus should be on disseminating good information to the public about road closures or the construction sequence.

Transportation policy makers and planners must also communicate what can and cannot be

decided through the engagement process. Many transportation parameters are mandated by federal or state legislation, which may limit the power of local actors or the public to influence the outcome of a project. Because transportation initiatives take place in a multi-jurisdictional environment, it can be difficult for community members to understand which agencies are responsible for which actions or to engage with the many agencies involved. Online methods, which are consistent with the rise of e-government and Web 2.0 government across many policy sectors, provide a promising platform for addressing regional-scale problems. They can connect geographically dispersed people who are affected by large-scale transportation policies but who may be unable to attend meetings because of the distance.

Engaging Expert and Other Perspectives

A prominent challenge in transportation planning is how to engage both experts and everyday stakeholders in technically complex decisions. Administrators may worry that giving the public influence over decisions traditionally left to those with engineering or other specialized expertise will produce choices that do not adequately consider safety, equity, efficiency, environmental protection, and political feasibility. They may also be concerned about limiting their managerial discretion to act decisively as needs arise, or about the resistance that well-organized groups may mount when they have more complete information about projects. Making issues and choices understandable to the public so that they can be informed participants is another challenge.

The public's increasing involvement in transportation decision making also offers advantages that can improve technical decision making. Non-experts bring lived experience and empathetic understanding that can produce new data and new understandings of problems. Without this knowledge, experts may undervalue considerations that should enter into their decision-making process. In addition, when a transportation agency limits information about expert-decision parameters, it can fuel a perception that the agency is withholding information or changing the rules midstream, compromising the credibility of its decisions.

Well-designed public participation can help address these challenges and provide an avenue for

valuable public contributions. Charrette and online optimization tools, for example, do not require people to be able to read engineering plans or technical documents in order to understand a policy and provide meaningful input. Such techniques can bring varying perspectives to bear on evaluating policy options.

Enhancing Diversity and Equity

Across all sectors, including transportation policy making, diversity and equity in access to public engagement are particularly persistent concerns. In general, individuals of higher socioeconomic status are more likely to have the time, money, civic engagement skills, or Internet access to participate, and those with greater individual and collective social capital are more engaged or exert more influence. As a result, the individuals or organizations who participate in engagement efforts may not be representative of the opinions and knowledge of the public at large.

In transportation, low-income communities may have a disproportionately high interest in transit policy and planning discussions, such as those related to public transit services. To reach them, alternatives to the traditional public hearing—such as telephone surveys or gathering input at transit stations and other locations convenient to these constituents—may be necessary to gather their input. Purposeful efforts to provide outreach in multiple languages and to provide translators are important for reaching constituents who are not comfortable communicating in English. Public and nonprofit organizations frequently consider religious institutions to be an effective venue for reaching nonwhite constituents about public issues, but such a location should be adopted with care so that diverse stakeholders feel welcome through one means or another.

Another challenge is enlisting a sufficient level of diversity without classifying constituents into stakeholder groups that do not capture their full range of interests. The concept of the “public” is complicated and multifaceted in transportation. There are, for example, strong differences in the interests and preferred modes for public engagement of the “freight community” and the “passenger community” in infrastructure planning.

Similarly, bicyclists are not a homogenous group, and misunderstandings and controversies may

arise if recreational riders, those who commute and occupy a lane like other vehicles, and long-distance riders are all lumped together as a single interest group. Transportation professionals must also take care not to orient too intensively toward engaging organized special-interest groups, because that may exclude the general public and raise the risk that a vocal, and perhaps unrepresentative, minority could have undue influence on policy making.

Evaluating Public Engagement

The final step in the process is evaluating the public-engagement effort. Evaluation allows policy makers to learn from the implementation, so that they can enhance the current engagement effort and build long-term institutional capacity. While evaluation can occur when a process is already under way or over, it is important to include it from the beginning of the design process. What are the desired outcomes, and how will they be measured? The typical measure—the number of participants, and perhaps some demographic information about them—is not adequate for meeting and evaluating most of the goals of public participation.

Methods for evaluating public engagement are not well established, but some resources do offer a starting point. The standards introduced by ISTEA for public involvement provide a common reference point across the transportation sector in the United States.

The ISTEA standards are that engagement be early and proactive, that timely information be provided to the public, that there is proof of explicit consideration of the public input, and that the input of traditionally underserved communities has been sought and included. Other measurements could include the degree of learning achieved through the process, by both participants and conveners; changes in capacity to implement policies, as observed through changes in conflict or agreement among stakeholders; and the overall quality of the final policy decisions in terms of their economic efficiency, safety, environmental impact, and political viability.

Public Transit Employees and Labor Issues

Public transit in the United States is a shared passenger transport service that is available for use by the general public. Forms of public transit include buses, trolleys, trams, trains, rapid transit (such as subways), and ferries. Public transit between cities and states includes airlines, intercity rail, coach bus services, and high-speed rail networks. No matter the type of vehicle or infrastructure within which the vehicle must travel, public transit employees face similar working conditions and stresses on the job.

Historically, some public transit employees have also faced forms of discrimination. To improve working conditions and compensation, and reduce discrimination in the industry, unions have formed to protect the interests of public transit employees.

At the same time, pay and benefit inequities exist between public transit employees who work for the city, county, or state and those employed by private companies, who, without unions to bargain on their behalf, may be paid less and receive fewer benefits.

Therefore, to cut costs, some governments are looking toward private, nonunionized companies to staff public transit services. While the long-term effects of such practices remain unknown, transit unions and other advocacy groups are committed to the idea that properly compensated, trained, and protected public transit employees provide better customer service and safer travel.

Public Transit Employee Categorization

The American Public Transit Association (APTA) identifies all public transit employees as operating employees, or anyone engaged in the operation of the transit system. APTA classifies operating employees in four categories. General administration employees manage and administer activities such as transit system development, system development, customer services, promotions, market research, injury and damage claims, safety, personnel administration, finance and accounting, and space management. Nonvehicle maintenance employees engage in support to vehicle maintenance employees, the third category, which is comprised of those who inspect, maintain, and repair vehicles. Last but not least, vehicle operations employees are the drivers, pilots, train conductors, ferry captains, fare collectors, and those engaged in system security activities. They make up the vast majority of operating employees in the United States.

Commuters in urban areas, as well as long-distance travelers, depend heavily on vehicle operations employees and vehicle maintenance employees to get them to their destinations safely and on time. Public transit also employs capital employees—those whose labor-hour cost is reimbursed under a capital grant, separate from the public transit employee budget.

Working Conditions

The public transit industry has particular employment issues that often bring the nature of the work and workers' rights into conflict. First, most vehicle operations employees interact with passengers.

Time-sensitive travel increases stress levels for both drivers and passengers, and customer-operator interactions can lead to conflict.

Second, vehicle operations employees—bus drivers, in particular—often do not have set times or places to take breaks. Transit agencies attempt to deal with this issue either by identifying the layover period as a break or by awarding drivers a lunch break once they reach their terminal destination. Vehicle operations employees also do not have the freedom to take bathroom breaks as frequently as they may require.

All public transit employees—particularly vehicle operations employees—face the phenomenon of split shifts. Most transit systems provide more services during peak commuting hours than at other times. For vehicle operations employees who work during peak hours, there may be no work in the middle of the day. Such drivers could work three to five hours in the morning, have anywhere from a one- to three-hour break, then work three to five hours in the afternoon. The “break” is unpaid, and the driver is not free to go home because their work day has not ended.

According to the Bureau of Labor Statistics, the transportation industry had the greatest number of days missed from work due to injury and the second-greatest number of fatal accidents. Many injuries result from long hours spent in uncomfortable seats, as well as assaults on operators by passengers. Absenteeism also continues to be a major problem in the public transit industry. Job stress and burnout cause many transit operators to abuse alcohol or drugs, which puts them at risk for job termination.

History

In the 19th century, stagecoaches served as a common mode of transportation for long-distance travel. Four to nine passengers could sit in the coach, depending on the model, and the coach driver would sit outside the cab to steer the horses. Coach drivers worked long hours under extreme weather conditions, and in the days when they had to cross the American frontier, often had to take the law into their own hands if approached by bandits or unfriendly Native American tribes. Most frequently, however, the stagecoach driver had to monitor passenger behavior and evict drunk, unruly passengers from the coach.

While horses were entitled to a four-hour workday, the men who drove them were expected to work an 18-hour day. These transit workers received no better treatment on the job than the vast majority of their passengers. Many lived in poverty with no health benefits, no holidays, no pension, and no job security.

Once the railroads connected the continental United States, the stagecoach disappeared as a mode of public transit, and in the late 19th century, various forms of street train systems emerged in major cities to transport the multitudes of poor laborers to and from work. Street train conductors and associated railway employees faced multiple challenges on the job that affected their safety and quality of service.

First, street trains ran on electricity. In the early days, blackouts could affect the timeliness of service, and that angered the riders. Second, lack of train safety education often led to fatalities for the railway employees, passengers, pedestrians, horse-drawn carriages, and other vehicles.

Early Labor Organization

In 1882, the first street railway union, the American Street Railway Association, was founded in Boston. Members of this union lobbied the city for increased safety precautions, more routes, and improved track maintenance. In 1883, the Knights of Labor Local 2878 was the first street railway labor union established in New York. The Knights of Labor was the largest and one of the most powerful labor organizations in the 1880s; the union's successful railroad strikes for eight-hour work days and improved working conditions led to a surge of union membership among railway workers.

However, it was dangerous for transit employees to belong to a union. For example, company spies were known to infiltrate union meetings and fire officers and all attendees. In 1885, transit unions across the United States drafted employment contracts for their members and demanded that they be signed by employers. If the workers' demands were not met, they would strike, thus shutting down service until their needs were met.

In 1892, transit union leaders organized a national convention to bring all of the transit unions together under a common name. The Amalgamated Association of Street Railway Employees of America—the first national union for public transit

employees—was established at this convention in Indianapolis, Indiana. This union is now called the Amalgamated Transit Union (ATU); it includes bus, train, subway, streetcar, and tram employees as its members.

Labor Laws

Due to aggressive union intervention and paralyzing strikes, the federal government passed many laws to improve labor conditions for railway employees. In 1898, the Erdman Act was passed to provide for mediation and voluntary arbitration for railroad workers, making it a criminal offense for railroads to dismiss employees or to discriminate against potential employees because of their union membership or activities.

In 1910, the federal government passed the Accidents Reports Act, which legalized a 10-hour workday and standardized pay scales and working conditions. In 1916, the Hours of Service Act reduced the workday from 10 to eight hours. In 1935, the federal government passed the Wagner Act, also known as the National Labor Relations Act, clearly establishing the right of all workers to organize and elect their representative for collective bargaining. The federal government also provided pensions and unemployment insurance for railroad employees. In 1952, the federal government ceased operation of the railroads, and other carriers took over. Nonetheless, employees and carriers reached an agreement on wage increases and working rules in a manner consistent with the existing federal laws.

Transport Workers Union of America

In 1934, the Transport Workers Union of America (TWU) was founded in New York. Originally, the union was comprised of workers from New York City's Interborough Rapid Transit (IRT) system. Unlike other unions of its time, the TWU's leadership refused to discriminate against any transit employee based on race, religion, gender, sexual orientation, or nationality. In the early 1930s, the TWU reserved porter jobs for minority workers discriminated against by every other union and fought hard to open up job opportunities for everyone.

In 1937, within a span of just six months, the TWU organized the entire New York City transit system. It signed six major contracts, which included unionization of two subways and 35,000

workers. In the early 1940s, transit workers from New York, Ohio, Nebraska, New Jersey, and Pennsylvania joined the TWU to fight for better health benefits, competitive salaries, nondiscrimination in employment, and increased professionalism in the industry. Today, most states have TWU chapters for airline, transit, railroad, and gaming employees.

United Transportation Union

In 1968, the Brotherhood of Railroad Trainmen, the Brotherhood of Locomotive Firemen and Enginemen, the Switchmen's Union of North America, the Order of Railway Conductors and Brakemen, the International Association of Railroad Employees, and the Railroad Yardmasters of America voted to approve their merger into the United Transportation Union (UTU). UTU is an AFL-CIO affiliate headquartered in North Olmsted, Ohio, representing 125,000 active and retired railroad, bus, and mass transit workers in the United States and Canada.

Other Protections

Public transit employees are highly concerned with safety because safety or security violations affect not only their performance but also their own personal safety. Even so, their complaints to their supervisors about major safety or security issues once went unheard, or the worker could even be punished for complaining. For this reason, the U.S. Department of Labor's Occupational Safety and Health Administration (OSHA) provides whistleblower protection for public transportation agency workers who want to report a safety or security issue. Public transit employees are protected under the 2007 National Transit Systems Authority Act (NTSA), 6 U.S.C. §1142, establishing retaliation protections for public transportation agency workers. Employees of providers of school bus, charter, or sightseeing transportation are covered under the Surface Transportation Assistance Act of 1982 (STAA).

To understand the drive to unionize among transit workers, consider the case of nonunionized workers with similar jobs and skills. For example, school bus drivers may work for a school district or a private company, but they tend to receive minimal or no training on the safe operation of a school bus, or on how to interact with student passengers. Quite often, the school bus drivers have

no union protection and no way to defend themselves from the assaults of their passengers. Fifty-five-year-old Gregory Davis, a school bus driver in Richmond, Virginia, filed a lawsuit against the Richmond City School District for unjustified termination after several student passengers attacked him while driving. Although the students were charged with assault, the school district based its decision to terminate Davis on a Virginia code that stated that public school employees may be suspended if their behavior threatens the safety and welfare of students.

Employment Discrimination

Historically, racial and gender discrimination has existed in the American public transit industry. People of color have often been barred from serving as train conductors and flight attendants; to this day, the majority of flight attendants are white. Women remain underrepresented as pilots, although this may change with the increasing number of female Air Force veterans returning to the civilian workforce. Increased diversity within the public transit employee population came from state and federal civil rights legislation.

Public transit union leadership is diverse, reflecting the union membership. The Transport Workers Union (TWU) of the AFL-CIO has stated its commitment to supporting diversity and ending discrimination. In 1961, TWU President Michael J. Quill introduced Reverend Martin Luther King, Jr., as a speaker at the organization's annual national convention as a gesture of the union's support to eliminate discrimination within the bus companies and to fight against segregated busing in the South.

Today, TWU also has special committees to address issues related to women and veterans employed in the airline industry. Yet, at the time of this writing, TWU has no specific body to address equity issues based on race or sexual orientation and gender identity. The Amalgamated Transit Union (ATU) has a diverse union leadership, but aside from providing policies that address how ATU will handle sexual harassment, the organization has made no statements as to how the union will defend employees against discrimination claims.

Historically, public transit employees have worn uniforms and have been subject to strict dress codes. As public transit employees become more

diverse in religious and cultural beliefs, they will want to wear head coverings, hair styles, facial hair, or other attire that does not comply with the company dress code. Multiple lawsuits have been filed by public transit employees against employers who told them they could not wear crosses, nose rings, or long skirts instead of trousers.

Public Transit Employee Benefits

In the 21st century, transit employees who work for the city, county, or state are considered city, county, or state employees. They are subject to the same antidiscrimination policies as other employees, and their pay scale is determined in negotiations between their union and the city, county, or state transit authority. Full-time public transit employees receive health benefits, sick leave, vacation time, overtime if they work more than the allotted hours within their shift, and some type of retirement package or pension.

The American Public Transportation Association (APTA) is an advocacy organization focused on the advancement of the transit industry. It represents public transit employee and administration interests at the federal level, organizing public transit systems to lobby on matters related to federal assistance, regulations, compliance, policy, and legislation. APTA collects information on public transit industries and provides a voice to the media on public transit issues. It has a scholarship program for students interested in pursuing public transportation as a career field and provides opportunities for networking. APTA also offers workshops and conferences to provide training on technological, legal, policy, and promotional updates in all areas of public transit. Most importantly, APTA seeks to improve security on public transit for the safety of employees and passengers.

Privatization of Public Transit Services

Many governments, in response to budget cuts, rising costs, and declining productivity, have considered or implemented the privatization of public transit to improve cost-effectiveness. Supporters of transit privatization claim that publicly owned, state-subsidized transit operations are inefficient because of their higher labor costs, restrictive work rules, and large bureaucracies. Critics of privatization insist that market failures counteract the benefits of privatization, resulting in under-insurance,

Track workers with the Metropolitan Transportation Authority of New York repair subway rails on August 9, 2013. According to the Bureau of Labor Statistics, the transportation industry had the greatest number of days missed from work due to injury as well as the second-greatest number of fatal accidents.

inconsistent vehicle maintenance, higher accident rates, and other deficits.

Contracting is the most common form of privatization in the United States. It allows the public agency to handle planning, routes, and scheduling coordination, while the private companies own, maintain, and operate vehicles, and hire labor. Private companies will aim to provide the lowest cost for service and the highest level of efficiency in order to compete with other entities for the contract.

Up until the 1960s, most bus transit firms in the United States were privately owned. Rapid growth in automobile usage caused ridership to decrease, especially for off-peak and weekend trips. In response to the increasing financial troubles faced by bus lines, the federal government passed the Urban Mass Transportation Act (UMTA) in 1964.

UMTA increased federal involvement and funding for failing transit firms. As subsidies increased, the cost of transit continued to rise faster than inflation, while productivity declined.

Traditionally, cost-efficiency in privatization of transit services was achieved through a non-unionized workforce. Today, private transit companies cannot deny employees union membership, although their wages may still be lower. The majority of cost savings that come from privatization come from leaner health care and retirement benefits of contracted employees.

Because state and federal policies aim to ensure transit access for the poor and disabled—as well as the general public—public agencies will most likely continue to maintain adequate service coverage and low fares. At the same time, privatization will cause salaries and benefits of public transportation employees to decrease.

Automation of Public Transit Services

To increase cost-efficiency, certain public transit jobs have been eliminated and replaced by automation. Human ticket sellers, as well as ticket collectors, are being replaced by ATM-like machines that allow riders to electronically transfer money onto a swipe card. This card gets swiped by the passenger either upon entry to a train platform or when entering a bus. While this type of system has reduced the number of public transit employees working in stations and the vehicles themselves, it has made rides more likely to run on schedule by reducing customer-driver interactions.

Human vehicle operators are concerned that a time will come when there is complete automation of transit vehicles. Vancouver, Washington, currently has the world's largest system of driverless metro trains. If an emergency takes place on the train, anyone on board can press an emergency intercom button and speak with someone in a central control center. In some other countries, automation is being combined with personalization in mass transit. Personal Rapid Transit (PRT) depends on fully automated "podcars" programmed to run on a track at particular times, stop at the station for passengers who indicate their need to get on, and then stop at the desired destinations of those passengers.

In 2013, the U.S. Department of Transportation began to solicit input on "surface transportation system automation," which would eliminate human vehicle operators. Unions are defending the rights of their employees to continue working in transit careers and are doing their best to protect their interests in this new technological age.

Queuing and Shockwave Measurement

A queue is a group of people or vehicles waiting for their turn for something—whether to be served by a cashier when queuing up in line at a retail store or to pass through an intersection. A queue can either be formal and organized, as with the first-come, first served line to purchase a bus ticket, or informal and disorganized or self-organizing, as with the jumble of people rushing to board an arriving bus. Queuing is the handling and organizing of the waiting elements of a queue. A police officer or other official directing traffic with a hand-held stop sign at the site of utility work or an accident is queueing traffic directly, for instance.

Queuing theory is the mathematical study of queues and the construction of mathematical models and simulations in order to investigate the effects of different actions, choices, or traffic events or features on queue lengths and wait times. Queuing theory, which originated in telecommunications, has applications in numerous areas (it is used in the design of hospitals and hospital procedure, for instance), and is especially important in traffic engineering.

Shockwaves

Shockwaves are propagating waves caused by an abrupt change to the medium through which they

pass (in mechanics, a “shock” is a transient excitation caused by a sudden acceleration), and resulting in a rapid rise of density to the flow of that medium. The properties and behavior of shockwaves can be examined and discussed independently of the environment in which they occur—that is, behaviorally, the shockwaves in the air caused by a detonation and the shockwaves in traffic caused by a traffic jam share important characteristics with each other.

In traffic, shockwaves are a result of queuing in congested conditions, and are propagating waves that move through traffic, noticeable in transition changes experienced sequentially by drivers as they are suddenly able to accelerate again after an idle period, or must slow down or stop again after a period of normal speed. While posing an inconvenience to drivers and resulting in inefficient fuel use and greater wear and tear, shockwaves more importantly pose a safety concern because of the increased opportunities for rear-end accidents.

From the right perspective—usually outside the car, unless traffic is going up or down a slope—shockwaves are visible as a cascade of brake lights. The transition change is caused not simply by the affected car passing into a part of the roadway where the capacity has changed. Rather, the lead car in the queue passes through an area where capacity has changed—perhaps because of a lane being shut down for an accident or because of an

Traffic backed up by an accident in New Britain, Connecticut, in September 2007. Rubbernecking at the scene of accidents or other road incidents can exacerbate shockwaves in traffic and can cause accidents. One study found rubbernecking to be the cause of 16 percent of distraction-related accidents in the era before smartphones and texting became a serious problem as well.

intersection or traffic signal—and in stopping or slowing because of that change, causes following traffic to stop or slow.

Shockwaves may be caused by capacity changes such as an increase or decrease in the number of lanes or an accident causing an obstruction, merging traffic, intersections, or traffic signals. However, it is important to note that heavy traffic is itself sufficient to cause shockwaves, since roadway capacity is a function of drivers as well as of the driving environment.

Shockwaves can affect drivers so far removed from the initial cause of the slowdown that it has been resolved by the time the farther-back drivers reach the incident area. Drivers are more likely to notice shockwaves that impede their travel, but increasing capacity in heavy traffic will also result in shockwaves of drivers being able to accelerate to greater speeds as the traffic ahead of them becomes less congested and the tight knot of the traffic jam loosens and frays.

Bottlenecks

Portions of a roadway where the capacity drops significantly relative to proximate sections of the same roadway are called bottlenecks, with the classic example being the narrowing of the roadway when the number of lanes is reduced, such as when approaching a bridge or tunnel or passing by an area of road construction. While traffic jams are caused by heavy traffic, a bottleneck is a specific reduction in capacity as a result of physical features of the roadway and can cause noticeable shockwaves even in light traffic. Some bottlenecks are the result of poor design, such as when a curve is too sharp and requires drivers to slow down substantially, or when traffic lights are badly timed and interfere with the steady rhythms of healthy traffic. Other times they are unavoidable temporary conditions, either because of an obstruction like construction or an accident, or because an especially busy traffic period (rush hour, or the Friday of Labor Day weekend) exceeds the roadway capacity. Bottlenecks are

vulnerable not only to traffic and safety issues but to security ones, and are frequently military targets.

Common causes of bottlenecks are the temporary closure of lanes due to construction or accidents, the narrowing of a multilane highway to a smaller number of lanes, poorly timed traffic signals; or slow-moving traffic. Slow-moving traffic can be caused by “rubbernecking,” which is a serious traffic ill. As drivers pass the site of an incident, whether an accident that caused a slowdown or a car that was pulled over by a patrol car or anything else, they slow down in order to have a better look at what happened. Even apart from the possibility that rubbernecking will itself contribute to accidents because drivers are distracted (and are changing speed at a time when drivers behind them are also distracted), it is a practice that exacerbates shockwaves in traffic. One study, conducted before smartphones and text messaging were popular in the United States, found rubbernecking to be the cause of 16 percent of distraction-related accidents. While its share is likely smaller now, it still has a substantial effect.

Traffic may slow for other reasons, though, particularly on one- or two-lane streets, where a single vehicle may be sufficient to slow the flow. This is often called a “moving bottleneck.” For instance, in farming communities tractors may slow traffic because their maximum safe speed is so much less than the posted speed limit on most roadways, and they are often too wide to pass even under normal passing conditions. On streets without sufficient shoulders, a mail delivery truck or newspaper deliveryperson may slow traffic unable to pass, by making frequent stops and having little opportunity to accelerate between them. And, of course, sometimes a driver is simply slow and impedes traffic behind him or her. Moving bottlenecks do not always result in shockwaves, though it depends on the roadway and the cause—here, the shockwaves would most likely be experienced by the traffic behind the mail truck, might be experienced briefly by the following traffic farthest behind the tractor in approaching the slowdown.

Analysis

To some degree shockwaves are unavoidable, at least without building roadways with capacities much greater than might ever be needed. Differences in speed contribute to shockwaves in traffic, for

instance. While most cars can respond to changing conditions such as a red light, merging traffic, or congestion up ahead in roughly the same time, smaller and lighter cars can respond more quickly without jolting their passengers, while tractor-trailers, buses, and other large vehicles require rather long distances to stop.

The speed of a shockwave is the speed at which the traffic disturbance associated with it is propagated through the traffic system. The speed of shockwave U_w is given by the formula:

$$U_w = q_c - q_B / k_c - k_B$$

Where q_c and q_B are the traffic flow rate of two sets of traffic conditions (c and B) and k_c and k_B are the densities in vehicles per mile of those conditions.

The usual description of traffic shockwaves as alternations between two states of driving (idling and free flow) is based on the classical conception of traffic as consisting of two phases free flow and congestion. Boris Kerner introduced an alternative three-phase theory in the late 1990s, proposing free flow, synchronized flow, and a wide moving jam (though “width” here is really referring to the length of the traffic jam end to end, not the number of lanes in which it transpires). In Kerner’s model, the “wide moving jam,” or J phase, is a disturbance in the traffic flow that moves upstream through bottlenecks and experiences numerous shockwaves. The synchronized flow, often with a downstream front at the bottleneck, is a continuous flow that might experience minor disturbances but nothing major, in which vehicle speeds become synchronized. This is a result both of the bottleneck that forces at least the fastest vehicles to slow down and of circumstances that make passing less likely.

One of the reasons the three-phase model is relevant is because it offers different explanations for traffic jams that are not caused by an obstruction, narrowing, or rubbernecking. Within the synchronized flow phase, narrow moving jams (minor perturbances) emerge in “pinch” regions where average vehicle speed slows down while vehicle density increases. These narrow moving jams can become J phases if they continue to grow or develop too close to one another.

Rail Corridor Congestion

Well into the second decade of the 21st century, United States national transportation policy remains shaped by a law passed in 1956. The Federal Highway Act of 1956—Dwight D. Eisenhower’s System of Interstate and Defense Highways—created the blueprint for the present roadway system in the United States and, along with it, changed the economic face of North America. The highway system forever altered rural areas, while expanding industry at a pace that was unprecedented. The highway, rail, and aviation networks have fostered new communities and connected cities, towns, and regions.

After more than 60 years and billions of dollars of investment, the United States has developed the world’s most advanced highway and aviation systems. Yet, these systems face mounting congestion and rising environmental costs. Moreover, the current transportation system consumes 70 percent of the nation’s total oil demand—much of it from overseas sources—and contributes 28 percent of its greenhouse gas emissions.

Current Challenges

While there is much attention in the United States focused on air-travel congestion and the high cost of fuel for highway driving, a crisis has also been developing for the transportation system used to

deliver most of the freight and many of the inter-city commuters in this country: the railroad system. North America’s 233,000-mile (375,000-kilometer) network of rails, devoted to carrying everything from passengers to grain and coal, is already under the strain of congestion.

The problem of tracks shared between freight and passenger trains has worsened in recent years as freight traffic has soared. Passenger trains move much faster than most freight trains, and in many areas there is only a single track, forcing trains to pull over onto side tracks and wait while trains coming in the other direction pass. Bottlenecks are increasing in many regions across the country.

The United States once had a thriving intercity rail and rail-based urban transit network. By the 1950s, however, the federal government shifted its infrastructure spending to highways and airports. Mass public transportation systems atrophied, and America’s technological leadership in the manufacture of everything from subway cars and trams to high-speed trains passed to companies in Japan and in France, Germany, and a few other European countries.

The loss of these industries in the 1970s and 1980s was largely a function of unstable demand rather than of high labor costs. As domestic demand for transit vehicles waned, U.S. companies did not keep up with state-of-the-art transit technologies. Continued underinvestment in infrastructure and

sustainable transportation options, meanwhile, left roads and bridges crumbling, mass transit systems in disrepair, and a transportation sector that accounts for almost one-third of our nation's greenhouse gas emissions.

Each year, traffic congestion costs Americans nearly \$90 billion in lost productivity and fuel purchases, with the average commuter losing nearly one full workweek sitting in traffic. Nearly half of all Americans lack alternatives to private automobiles and convenient access to public transit, which makes congestion even worse. Meanwhile, the lack of fully coordinated railroad investment means that, even with passenger rail traffic down, the improvements to the freight rail system have in many cases been undermined and stalled.

The existing public transit infrastructure suffers from decades of deferred maintenance. A recent report by the U.S. Department of Transportation (USDOT) found that the nation's public transit systems would need an immediate investment of over \$77 billion just to bring them into a state of good repair.

It is clear that the existing infrastructure is insufficient to handle the country's future passenger and freight mobility demands. An approach is needed that responds to economic, energy, and environmental challenges. The strategic goals as laid out by the U.S. government are to ensure safe and efficient transportation choices, build a foundation for economic competitiveness, promote energy efficiency and environmental quality, and support interconnected livable communities. Under this rubric and the new policies instituted through more recent legislation, freight rail corridor congestion in the United States is attracting more funding, and a turnaround may be in sight.

Legislation and Effects

In 1980, the Staggers Rail Act went into effect under the auspices of the Interstate Commerce Commission, now operating as the Surface Transportation Board (STB). This was largely a deregulation initiative designed to unlock the capacity of the U.S. private freight rail industry to expand, increase profits, and deliver higher quantity and quality of service.

The goals of the Staggers Rail Act are considered to have been achieved; for example, the metric of revenue-ton-mile is instructive, as data compiled by the Federal Railroad Administration (FRA) shows.

In the 30-year period of 1950 to 1979, railroad market share of revenue-ton-miles had decreased from 56.1 percent to 37.5 percent, with the market share shifting mainly to trucking and to waterborne and pipeline transportation modes. In the three decades between 1980 and 2010, railroad market share of revenue-ton-miles stabilized and edged up to more than 40 percent. This is the largest market share of any freight mode.

Regarding utility by distance, the FRA data indicate that rail is particularly dominant in the shipment of freight within the 500-mile to 1,500-mile (800-kilometer to 2,400-kilometer) sector of the freight industry. Rail also dominates in the transport of freight categories of bulk goods, manufactured goods, and consumer durable goods.

During the post-Staggers period, annualized improvements to both track and equipment have grown substantially, with more than \$500 billion invested cumulatively by the private freight rail companies, while rail accidents have declined by more than two-thirds. At the same time, freight rates halted their inflationary trend and have shown an average decline of 0.5 percent annually—even while freight rail company profits have increased.

By 2010 the U.S. freight rail industry comprised some \$60 billion in economic activity and shipped approximately 12.5 billion tons of freight per year. Projections by the STB were for 14.7 billion tons of rail freight in 2030 and 16.9 billion tons in 2050. These projections of increases of 22 percent and 35 percent, respectively, were based on a steady annual rate of 40.3 tons per capita, and of U.S. population increases to 366 million by 2030 and 420 million by 2050.

In 2009, President Barack Obama signed into law the American Recovery and Reinvestment Act (ARRA). As part of this legislation, the FRA has been charged with the distribution of \$8 billion for intercity and high-speed rail projects. The FRA has pledged to employ impartial evaluation criteria to judge applications (from all states applying), and to allocate this funding to only the most appropriate projects. The agency has outlined specific transportation, job recovery, project readiness, and other public-benefit criteria on which these applications are to be judged.

Defining which corridors are most appropriate for high-speed rail development is critical for the long-term success of this new federal program. The

\$8 billion appropriated for high-speed rail in the ARRA legislation is only a small fraction of what will be necessary to fully construct an American high-speed rail network.

Further, to maintain public support for a continued federal commitment to high-speed rail, the initial investments must be viewed as a success. There are huge potential financial risks inherent in any large-scale transportation infrastructure project. However, investing in corridors with the maximum potential to support such systems reduces this risk, increasing the probability of success and long-term public support.

It is helpful to clarify exactly what may be funded under this new program. There is no authoritative definition of what constitutes high-speed rail—and not all projects eligible for ARRA funding meet the definition of what international competitors consider high-speed rail. The European Union defines high-speed rail as separate lines built for speeds of 150 miles per hour (250 kilometers per hour [kph]), existing lines upgraded to speeds of 125 miles per hour (mph) (200 kph), or upgraded lines where speeds are constrained by circumstances such as topography or urban development.

In its “Vision for High-Speed Rail in America,” the FRA provides three definitions of high-speed service based on (1) distance between markets, (2) top speeds of service, and (3) existence of dedicated rights-of-way. The FRA 2009 High-Speed Rail Strategic Plan also defines three categories of high-speed-rail (HSR) corridors.

These categories are defined in terms of top speeds, track characteristics, and service frequency: (1) Core Express HSR corridors are up to 600 miles (960 kilometers) in length, achieve top speeds of at least 150 mph (240 kph), and use grade-separated track dedicated to passenger service in major population centers. (2) Regional HSR corridors are 100 to 500 miles (160 to 800 kilometers) in length, achieve top speeds of 110 to 150 mph (180 to 240 kph), and use dedicated and shared tracks to serve mid-sized urban areas and smaller communities. (3) Emerging HSR corridors are 100 to 500 miles (160 to 800 kilometers) in length, achieve top speeds of 90 to 110 mph (145 to 180 kph), use shared tracks, and serve moderate population centers and smaller, more distant areas. These services are also expected to be very competitive with air and auto trips in these markets.

The major effects on freight rail operations by implementation of the FRA plan could stem from new, streamlined railroad rights-of-way and the improvement of existing rights-of-way where congestion is at its worst. The lion's share of investment in freight-specific rights-of-way, however, is expected to originate from within the freight rail industry's companies and private investors. Still, every improvement in passenger rail corridor engineering and operations will yield the net effect of enhancing freight rail operations along those regional lines and systems. Additionally, the location and scale of various improvements to passenger rail facilities will impact the decision-making analysis of freight rail infrastructure, particularly as to the siting and engineering of intermodal freight handling, which has already become one of the most critical areas of freight rail investment.

The FRA, for its high-speed plans, has strategically invested in five megaregions: Seattle-Portland, Oregon; San Francisco-Los Angeles, California; North Carolina's Charlotte and Raleigh to Washington, D.C.; the Midwest Hub; and the Northeast Corridor. Collectively, these areas hold some 65 percent of the country's population, cover 33 states and the District of Columbia, and stand to absorb the bulk of future population growth. Each of these regions will be key to the future development of freight rail in America.

Recent Investments and Additional Programs

The United States has an opportunity to invest in public transportation and renew its manufacturing base. This country could gain more than 79,000 jobs in rail and bus manufacturing and related industries under an investment strategy that could double transit ridership in 20 years. If the United States were to invest at even higher levels—similar to those of China—this could yield more than a quarter of a million jobs.

The impact on freight rail will be similar in its growth potential across the United States. For example, some 221,000 jobs already are directly or secondarily created and funded through the freight rail industry, according to the FRA. These workers are employed largely by the country's seven Class I railroads (operating revenues over \$433 million) and by 21 regional and 510 local railroad companies.

It is not too late for the United States to follow the strategy of European nations and China in building a strong transit-vehicle industry. If more stimulus funds were directed to rail infrastructure and to public transit, the United States could develop world-class public transportation and create highly needed jobs, while helping to reduce urban traffic congestion and greenhouse gas emissions in the nation's cities.

The Transportation Investment Generating Economic Recovery, or TIGER, Discretionary Grant program provides a unique opportunity for the USDOT to invest in road, rail, transit, and ship port projects that promise to achieve critical national objectives. Congress dedicated \$1.5 billion for TIGER I, \$600 million for TIGER II, and more than \$526 million for TIGER III. Eligible projects include freight rail projects and high-speed and intercity passenger rail projects.

As of 2013, the FRA was administering more than \$328 million in TIGER funds. The program enables the USDOT to use a rigorous process to select projects with exceptional benefits, explore ways to deliver projects faster, save on construction costs, and make investments in the nation's infrastructure that make communities more livable and sustainable. Further benefits accrue both nationally and regionally as the private-industry owners and operators of freight rail systems are able to tap into, adopt, and adapt for their needs many of the technological and engineering achievements attained in the pursuit of these improvements to passenger rail. This is, in effect, a direct force multiplier as the environmental, economic, jobs, and quality-of-life improvements are accelerated through better planning, construction, operation, monitoring, and upgrading of the freight rail infrastructure that supports more communities also served by the improved passenger rail networks.

Managed by the Federal Transit Association's (FTA) Office of Research, Demonstration and Innovation, the Transit Investments for Greenhouse Gas and Energy Reduction (TIGGER) program works directly with public transportation agencies to implement new strategies for reducing greenhouse gas emissions and/or reduce energy use within transit operations. These strategies can be implemented through operational or technological enhancements or innovations. Initiated within the American Recovery & Reinvestment Act (ARRA) of 2009, the TIGGER program continues to support public transit

agencies for capital investments that will reduce the energy consumption or greenhouse gas emissions within their public transportation systems. Demand for TIGER and TIGGER grants far outstripped the resources available, with the USDOT receiving over 1,500 proposals that totaled more than \$58 billion, despite initial allocations of just \$1.5 billion for TIGER and \$100 million for TIGGER.

The National Cooperative Rail Research Program (NCRRP), initiated in spring 2012, was authorized as part of the Passenger Rail Investment and Improvement Act of 2008 (PRIIA) to conduct applied research on problems that are shared by freight, intercity passenger (including high-speed rail), and commuter-rail operators. The NCRRP undertakes research and other technical activities in a variety of rail subject areas, including design, construction, maintenance, operations, safety, security, policy, planning, human resources, and administration. The program is sponsored by the FRA, with program oversight provided by an independent governing board (the NCRRP Oversight Committee) appointed by the secretary of the USDOT.

Under all of these programs, the Transportation Research Board of the National Academies (TRB) organizes panels of experts to provide guidance on technical aspects of the research and to translate the problems into project statements with well-defined objectives. Research proposals are then solicited from private and public research organizations with capability and experience in the problem areas to be studied. The technical panels review the proposals, recommend contract awards, monitor research in progress, provide technical guidance, and determine the acceptability of the final reports. More than 3,000 experienced practitioners and research specialists currently serve on Cooperative Research Program panels.

Global Outlook

In the face of challenges such as high gasoline prices, traffic congestion, and carbon footprints, public transportation offers a range of benefits over private automobile travel.

Unfortunately, the United States lags behind China and many other countries both in maintaining and expanding its public transit infrastructure, as well as in creating the high-paying manufacturing jobs that can go along with this investment. Four nations that have retained significant manufacturing

employment in the rail and transit industries are Germany, Spain, Japan, and China.

China planned to spend nearly \$293 billion to meet its 2012 goals for high-speed rail and other rail and transit expansion. In addition to a world-class train network, China is using the initiative to create 6 million jobs and generate demand for 20 million tons of domestic steel. China is expected to account for more than half of global rail equipment expenditures in coming years.

Germany is Europe's largest rail and transit market, and one of the largest in the world. Although the United States has almost four times the population of Germany, both countries have about the same number of mass transit passengers. Germany's rail manufacturing industry remains a global technology leader, with a foundation of strong internal demand and even larger export sales. Germany's per capita investments in rail and transit are double those of the United States. Direct and indirect jobs in rail manufacturing amount to almost 200,000; if rail construction and operations are included, the number rises to 580,000.

Spain is a highly progressive rail power, maintaining the largest high-speed rail construction program in Europe. It is benefiting from a marked increase in rail ridership. Rail travel increased 55 percent between 1990 and 2008, far outstripping population growth. The Spanish government's 2004 Strategic Plan for Infrastructures and Transport (PEIT) served as an innovative planning tool, calling for 44 percent of total transportation investment to be directed toward rail, primarily for expansion of the high-speed network. Spanish companies that provide goods and services exclusively to the rail sector employed about 116,000 people in 2008.

Japan has been a pioneer in high-speed rail development (first utilizing high-speed rail in 1964) and continues to be a global leader. However, the country's declining population will limit domestic demand for rail services. Japanese rolling stock manufacturers are looking increasingly to the burgeoning global market; exports accounted for 38 percent of their revenues over the past decade. Some 25,000 people are employed in the production of rail equipment, parts, and signal and safety equipment in Japan, with many times more employed in component-parts supply chains.

Except for China, these and other countries have entered the U.S. market to supplement the stable

internal demand for equipment in their own countries that resulted from significant investment in their rail systems. These leading railcar manufacturers include Bombardier (Canada), Kawasaki (Japan), Alstom (France), Hyundai-Rotem (South Korea), Kinkisharyo (Japan), and Siemens (Germany). To meet Buy America requirements, some foreign suppliers of parts and component systems have established permanent U.S. facilities, while others make temporary use of local subcontractors.

The United States is finally making a turnaround in its commitment to public transit, but the level of investment so far pales in comparison to that of many European and Asian nations. While ARRA represents a significant one-time boost to U.S. public transportation funding, it remains unclear how much in regular annual appropriations will be made available in coming years.

It is beyond question, however, that major investments that are magnitudes higher than current spending will be necessary, and must be carried out over several decades, to satisfy future needs. The United States needs to dramatically increase its investment in public transit infrastructure in order to build systems that increase ridership, help to reduce congestion in metropolitan areas, lower greenhouse gas emissions, and create much-needed manufacturing jobs.

Rail Transit Planning, U.S.

Rail transit systems are a diverse array of transport types using a fixed guideway or rail, each of which plays a different role in transportation in the United States. Whereas intercity passenger rail systems generally connect large metropolitan areas (for example, Amtrak between New York and Chicago) and are scaled to the national level, rail transit systems are designed to span regional or metropolitan areas. Commuter rail provides connectivity between an urban transportation hub and outlying communities (for example, the Long Island Railroad connects New York City with communities along Long Island), originally for the purpose of delivering workers to their jobs in the city. Light rail and subway systems more generally provide intraurban connectivity for people who need to get around within a city.

These classes of rail transportation differ not only in the scale at which their services are provided but also the frequency with which those services are provided. Rail transit systems generally run more frequently than intercity passenger rail; light rail and subway systems run more frequently still. However, they are all part of the intermodal urban transportation network that provides mobility alternatives

to the automobile for workers, shoppers, and travelers across the United States.

Planning for and implementing rail transit systems can be a lengthy and expensive process. However, improvements in federal transportation policy, coupled with present challenges of highway congestion and degraded air quality, have resulted in more flexible planning and funding processes that enable cities, regions, and states to more responsively and transparently plan for and implement these systems. Cities in which rail transit forms a large component of its transportation systems are characterized by significantly higher transit ridership and transportation system performance when compared to cities that have bus-only or no alternative transportation systems. Robust rail transit systems contribute significantly to the reduction of urban highway congestion and the improvement of regional air quality.

Background

A publicly regulated private market for transportation services originally dominated intra-urban rail transit systems. However, with the advent of and competition from the automobile and the post–World War II low-density suburbanization of the U.S. population, these transit systems became financially unsustainable. As ridership plummeted, the private transportation companies had increasing difficulty turning a profit, because their fares were constrained by public regulatory authorities and they were increasingly competing with cheap gasoline, rapidly improving highway networks, and the automobile. Because the cities had developed a reliance on these services to ferry workers from suburban communities to their jobs in the city, they were forced by circumstance to assume financial and operational responsibility for these networks when private companies failed. With no federal support for their maintenance or renewal, though, these systems began to decay, along with the fabric of the inner city.

In the 1960s, the federal government developed a formal interest in rail transit when cities asked for financial assistance in maintaining and improving those systems as part of their economic redevelopment activities. Seen as a uniquely urban problem, the first federal support for rail transit came in the form of urban development aid. The federal urban mass transportation program began in 1961 under

A New Jersey Transit sign marks a federally funded construction project to reopen a previously abandoned section of rail called the Lackawanna Cut-Off, which ran for just under 30 miles, beginning in Hopatcong, New Jersey. The project began in 2011 and a phase that is just over 7 miles long is expected to be complete by 2016, with the possibility of further extensions.

the U.S. Housing and Home Finance Administration, which became the U.S. Department of Housing and Urban Development (HUD) in 1965. The Urban Mass Transportation Assistance Act of 1964 provided the first dedicated public transportation funding; it was renewed in 1970. These programs provided grants for up to 50 percent of the cost of transit capital improvements.

In 1973, the Federal-Aid Highway Act allowed the flexible allocation of highway funds to urban mass transit projects. The 1974 National Mass Transportation Assistance Act, administered by HUD, allowed federal funds to be used for transit operating expenses as well as construction costs. The federal urban transit program was transferred to the Department of Transportation (USDOT) in 1968 and called the U.S. Urban Mass Transportation Administration (UMTA). It was only in 1991, with the passage of the Intermodal Surface

Transportation Efficiency Act (ISTEA), that the Federal Transit Administration (FTA) was created as a modal agency on par with the Federal Highway Administration.

Planning for Rail Transit

The contemporary need for a rail transit system arises from a number of sources. Urban sprawl development in the United States that came following World War II has resulted in a dislocation of the workforce from the workplace and highway congestion resulting from the necessary commute. It has become apparent in many major cities that a mobility policy predicated on building more highway infrastructure mitigates neither congestion nor air quality degradation. Cities are seeking alternative transportation solutions, including rail transit, that will demonstrably reduce traffic congestion, increase worker and shopper mobility, improve air

quality by reducing the number of cars on the road, and improve the overall quality of urban life.

Although bus systems are relatively inexpensive, and flexible from funding and routing perspectives, they have limitations in the volume of riders they can accommodate and the speed with which they can travel (over the same congested roadways plied by the automobiles they are meant to replace). Bus transport also suffers from a social stigma that has yet to be overcome in most municipalities.

Compared to bus transit, a rail transit solution requires significantly greater planning, incurs a much greater implementation cost, and requires more extensive supporting infrastructure. Further, because a rail transit network is rarely as dense as one achievable by a bus network, its success is dependent on the residential and business density in the vicinity of rail transit stations. Finally, because of the relatively limited number of stations in a rail transit system (compared to a bus transit system), its success is dependent on its connection to and integration with a denser network of bus transit.

Traditionally, the federal government has played a central role in providing financial support for urban transportation systems. However, it delegated planning, design, construction, operation, and maintenance of these systems to state and local authorities.

With the passage of ISTEA in 1991, the federal government shifted its emphasis from construction of the interstate highway system (by then nearly complete) toward roadway maintenance, as well as the development of more integrated transportation systems that could better serve diverse constituencies (including those in urban areas). The act encouraged intermodal transportation planning conducted at the local and state levels that more transparently engaged transportation system stakeholders and the private sector. More flexibility in spending funds previously dedicated to highways would be granted to projects developed to meet changing transportation demands reflecting economic, demographic, and environmental trends.

Metropolitan planning organizations (MPOs) arose in the 1960s as regional agencies were tasked by the federal government with creating long-range metropolitan transportation plans (MTPs) and short-range, prioritized capital investment plans (transportation improvement plans, known as TIPs). When contemplating a major investment

using federal funds, MPOs are required to conduct a Major Investment Study (MIS) exploring in detail the suitability and performance of competing design and implementation alternatives. Project proposals and planning initiatives eligible for federal financing assistance percolate up from the local/regional level through modally integrated MTPs and TIPs to the state transportation improvement programs (STIPs). The STIPs are submitted to the USDOT for evaluation and funding decisions.

Rail Transit, Development, and the Environment

In addition to its obvious contributions to a diverse and efficient urban transportation system, rail transit can play a large role in a municipality's sustainable development initiatives. A rail transit system can contribute to the reduction of automobile vehicle miles traveled (at least along the system's routes), aid in reducing urban highway congestion and the need for automobile parking in the urban core, and play a significant role in a city's portfolio of air quality management initiatives.

From an economic perspective, rail transit not only connects workers to their workplaces and consumers to the businesses they patronize, but it also provides a focus for residential, retail, and office location and development decisions. Just as land development often tends to concentrate around turnpike exits, commercial and residential development can be stimulated by the creation of stations along a rail transit route. Transit-oriented development (TOD) initiatives that specifically encourage such development have capitalized on the synergy between transit ridership and economic development by planning for the collocation of residential and commercial development around transit stations. As a result, many riders can reduce their dependence on the automobile.

Highway congestion and its concomitant increase in stop-and-go driving and engine idling have a significantly negative impact on air quality. The ISTEA of 1991 created the Congestion Mitigation and Air Quality (CMAQ) program (reauthorized in all subsequent surface transportation bills), which funds transportation projects or programs that will contribute to attainment or maintenance of the national ambient air quality standards for ozone, carbon monoxide, and particulate matter. The program enables metropolitan regions to

address transportation-related challenges to air quality through implementing congestion mitigation strategies. To the extent that transportation alternatives such as rail transit could aid in reducing the economic costs associated with urban highway congestion and improve regional air quality associated with that congestion, funding available through CMAQ can be allocated to these projects. Examples of projects that are eligible for funding with CMAQ funds include new transit facilities, new transit vehicles, and operating assistance for new or extended transit programs.

Present Funding

Prior to the 1980s, federal funding of surface transportation projects did not require that planners rationalize various transportation solutions into an integrated, multimodal surface transportation system. The first step taken to combine highway, transit, and safety authorizations came in 1982 with the passage of the Surface Transportation Assistance Act. In 1991, ISTEA created a unified surface transportation program with increased intermodal funding flexibility.

Congress has yet to designate a dedicated funding source for the mass transit account in the Highway Trust Fund (HTF) that was created in 1982 under the Surface Transportation Assistance Act. As eligible transit projects are designated for funding, monies are transferred from the highway account of the HTF to the mass transit account. When funds are transferred to FTA, they are allocated to one of three accounts: the Urbanized Area Formula Program, the Non-Urbanized Area Formula Program, and the Elderly and Persons with Disabilities Program.

The Move Ahead for Progress in the 21st Century Act (MAP-21) is the 2012 reauthorization of the 2005 Safe, Accountable, Flexible, Efficient Transportation Equity Act (SAFETEA-LU), the federal surface transportation funding legislation. The Federal Funding Transportation Act, part of MAP-21, restructured the federal transit program. It established goals for the federal transit program, which include the following:

- Increase availability and accessibility of public transportation
- Promote environmental benefits of public transportation

- Improve safety of public transportation
- Achieve and maintain a state of good repair of public transportation
- Provide an efficient and reliable alternative to congested roadways
- Increase the affordability of transportation for all users
- Maximize economic development opportunities

While these goals are not specifically incorporated into the programs, or the progress toward them measured, MAP-21 does move the federal transportation program toward a performance-based approach for funding recipients, including the use of performance measures for maintaining systems in a state of good repair, transit safety, and congestion mitigation and air quality.

Transit programs under MAP-21 also include provisions that promote TOD. These include the establishment of a national goal for the encouragement of mixed-use, transit-oriented development and the creation of a TOD planning grant pilot program.

Immediate Prospects

Ridership on intra-urban transit systems is at an all-time high. Unfortunately, federal funding for the creation, extension, operation, and maintenance of these systems remains contingent on the health of the Highway Trust Fund. Recent economic sluggishness and increasing fuel efficiency have reduced fuel tax revenue, which comprises 90 percent of the HTF, and those dips have required three federal general fund transfers since 2007 to keep the HTF solvent. Because the mass transit account of the HTF is funded by only 2.86 cents of the gasoline tax (compared to 15.44 cents accrued to the highway account), funding for rail transit projects is particularly threatened. However, because rail transit systems provide strong congestion mitigation, air quality, and economic development impacts, an increasing number of cities are moving ahead with the planning and construction of new systems or expansions of existing ones.

Rail Transit Planning, Worldwide

The invention of fixed-line railway transit in the 18th century revolutionized the way people traveled and how they lived. For example, electric streetcars substantially increased daily travel distances and allowed towns to expand to suburbs that profoundly affected the form of cities. Subways achieved very high carrying capacities without taking much land for a right-of-way, which revolutionized how millions of people traveled in central business districts.

Rail transit systems changed economies by crossing continents and connecting cities. They continue to impact the lives of people, markets, and the built and natural environment. Further, changes in railway technology have been mirrored by shifts in transportation planning approaches, as well as the policies that affect how rail transit systems are operated. A great deal of diversity in rail transit services affects both planning and policy in different countries, and vice versa.

The type of rail transit service involved has implications for planning and operations. There are two primary types of rail systems: light rail transit (LRT) and heavy rail transit (HRT). LRT, including streetcars and tramways, tends to serve relatively dense urban areas and can operate on tracks embedded in the roadway or in a dedicated right-of-way. Mixing trains with car traffic, while it can reduce right-of-way acquisition costs, substantially lowers operating speeds and thereby increases travel time. However, light rail can move more slowly and still serve the needs of the community because it serves stations located relatively close together.

HRT generally operates on dedicated right-of-way traversing urban, suburban, and rural areas. It tends to have trains that travel faster and serve stations spread over a greater distance. The right-of-way of heavier rail is often shared with freight trains, which can impact the operation of either service, depending on which has priority in the corridor. Heavy rail also includes monorails and rapid transit systems (that is, subways or metros), which are used primarily for transporting people in dense urban environments.

Railway systems also vary dramatically by other characteristics. A railway system can form an extensive network with different types of rolling stock connecting many destinations, or be stand-alone line operated by a single agency or company. Some railway transit systems are intended to specifically serve urban needs. This is particularly true for rapid transit systems and LRT that serve different areas of a city or metropolitan region. These types of railways can be at grade, elevated, underground, or a combination.

Rail Transit and Its Effect on Economies

Existing railways have been built within a specific political context, based on the needs and resources of the population or operator and adapted to the local built and natural environment. Most of the railway networks currently found in less developed countries (LDCs) were built by colonial powers to further their own economic and military interests. The end of colonialism removed railways' major source of financing, as well as some of the initial justifications for subsidizing their infrastructure and operations.

A lack of investment in renewal or even basic maintenance of rail systems has led many lines to become dilapidated, leaving the community with

no alternative transportation infrastructure, or service in place. More recently, though, emerging economies (for example, Brazil, China, and India) have invested heavily in rehabilitating and expanding their rail transit networks.

Even among developed countries, investments in rail transit have been mixed. Railways initially had significant impacts on the fate of U.S. towns—impacting development patterns and changing the built environment. A close connection between real estate development and rail investment can be traced to the earliest history of rail systems in many countries, including LDCs. An increase in access by new rail service would often lead to higher demand for land around stations, and possibly along the entire corridor, thereby increasing property values.

Regions' economies were changed by the access rail transit provided to both businesses and employees. However, many lines declined in the post–World War II era, when there were massive increases in road investments and automobile ownership. In the past few decades, though, there has been a resurgence of interest in using transit-oriented development (TOD). TOD combines the provision of rail transit with land use and real estate development so that the built environment around stations supports transit ridership, while the presence of stations enhances economic and social activities.

Many European countries and emerging economies have expanded their rail transit networks strategically, primarily by investing copiously in urban railway networks and high-speed railways. Urban transit systems have been built or extended when congestion on the existing transportation infrastructure is insufficient to meet current or projected demand. In the past five decades, several countries (for example, China, France, Germany, Japan, and Spain) have added high-speed rail networks—often on dedicated rights-of-way to separate these trains from slower ones. These long-distance lines have stimulated economic development (tourism, business travel, etc.) between cities, regions, and even nations.

Connecting these railway systems across national borders has traditionally been limited in many regions. Some countries intentionally designed railway systems to be incompatible with those of their neighbors in the interest of national security. Although many European countries have enhanced their cross-border connections, other nations have

been either unwilling or unable to make compatible systems. This has limited the opportunities for trade as well as for travel between countries, notably in infrastructure-poor Africa.

High Costs But Mixed Returns

Another key factor affecting the planning process for rail transit is cost-effectiveness. Large public transportation projects, including rail projects, are often found to have significant cost overruns, while performance and usage are often lower than projected. This results in substantially lower cost-effectiveness than expected based on planning studies.

The level of railway investment varies by its type and scale, availability of right-of-way, geographic conditions, and engineering specifications. In regard to intra-urban rail systems, LRT has been attracting substantial attention for its lower capital cost relative to HRT and the positive economic impacts anticipated for station neighborhoods and the transit corridor. Their outcomes, however, still vary significantly by place. Rail transit projects require a lot of capital investment for construction and maintenance, and, once built, many of them must depend on subsidies to operate their service. All of this adds up to a need for substantial public investment.

Evaluating the effectiveness of rail transit services in the planning process also often involves comparing them to competing modes, particularly road-based travel. Where roadway infrastructure is already developed and costs of owning and operating automobiles are not expensive, rail transit systems are not typically profitable, particularly those that provide passenger service. Moreover, motor vehicles can drive over poorly maintained roads and even unpaved surfaces, whereas trains require a well-maintained infrastructure or they risk derailment.

The fact that motor vehicle owners are responsible for their own operation and maintenance costs also makes this mode more appealing to those who balk at rail transit's need for public subsidies. The inability of most rail transit to cover even its operating costs has actually led to deferred maintenance and eventually to the need for costlier renewal projects. However, railways are recognized as one of the most environmentally friendly modes of transportation when used efficiently, especially when ridership is high. They also have the ability to provide more affordable transportation to users than if they had to own and operate their own vehicles. These

arguments have rekindled interest in rail transit in areas with the potential for high ridership.

While transporting passengers can be undesirable from an internal financial perspective, rail transit has also been justified based on its ability to stimulate the local and regional economy. The concept remains relevant in the idea of “value capture” approaches, through which the public sector aims at a recovery of at least part of its capital investment in the rail system, either through increases in tax revenue or directly through income generated on publicly owned TOD (for example, Hong Kong). However, the effectiveness of value capture depends on a number of factors, including the regional economy and real estate market, other transportation projects, local land use regulations, the local planning process, etc.

Planning Considerations

Regardless of the motivations behind the proposal, planning for new railway projects is a complicated and expensive endeavor. It generally involves preliminary planning studies and analyses of alternatives, environmental impact studies, and more detailed engineering studies. Funding for studies or construction can be secured from private sources and/or various levels of government at almost any stage of the planning process. Official hearings and public outreach are usually required and, in developed countries, their timing is often specified by regulation in order to ensure adequate consideration of varying viewpoints.

Given the significant levels of resources involved, as well as the myriad stakeholders who have different and sometimes competing interests, the planning and construction of rail transit can also be very contentious. Various constituents impact railway transit planning and policy decisions to differing degrees. Governments and their representatives (that is, public officials, experts, and bureaucrats) have played a large role in the planning, financing, construction, and even the operation of railways. Not only does government often decide whether to build railways it has played a central role in determining the type of railway to build and planning where the tracks and stations should be located.

Various public agencies help regulate railways once built, even if they are privately operated. Many countries’ national passenger railway service is provided by a public entity, and the same is often true at the regional and local level. Although politicians

and government officials may sometimes adequately represent the transportation perspectives of the society, the public is often called upon to directly express their perspectives in the planning process. Sometimes members of the public even sit on advisory committees as a means of providing feedback to transit agencies on their operations and policy changes.

The private sector has played different roles when it comes to rail transit. Private-sector promoters of early U.S. railway systems aimed to stimulate development by making transportation easier, cheaper, and faster. Many private interests built and operated passenger railway systems to make land more attractive for development. In some countries during the colonial period, colonialists lobbied their territories’ administration to construct new lines to better serve their interests. Although responsibility for the provision and operation of rail transit largely fell to the state after World War II, private-sector companies continue to participate in the planning, construction, and operation of many railway transit systems. In fact, the current trend has been to increase private-sector participation to the greatest degree feasible, given political, economic, and other practical constraints on governments.

This usually involves privatization wherein the government retains ownership of the right-of-way while a concessionaire takes responsibility for operations and even maintenance of the railway service. These concession deals can open up the right-of-way to multiple operators, which theoretically increases competition, reduces operating costs, and increases the benefits to users. Privatization can accomplish this when railway companies have more efficient management than the public sector, encourage the use of creative and innovative approaches to marketing and operations, and reduce labor costs by cutting staff size, eliminating unions, and replacing higher-paid unionized workers with cheaper labor. Given the effort to reduce operating expenses by reducing pay, staffing, and service levels, it is not surprising that governments and the public have often resisted privatization policies.

International development institutions (IDIs), which include both bilateral (for example, the U.S. Agency for International Development) and multilateral aid agencies (for example, the World Bank), have become important players in the provision and support of railways around the world. IDIs

became involved in rail transit issues for many reasons, including improving the allocation of public resources and stimulating development. They provide both capital financing and technical assistance to many governments that want to build, upgrade, or preserve their railway systems.

Occasionally, IDIs such as the World Bank have provided grants or loans to railway systems that have not been able to cover their operating costs. Critics have charged that countries that provide bilateral assistance have motivations that are not entirely altruistic. Tied-aid, where a certain portion of a financing package must be allocated to businesses from the loaning country, is common. The World Bank has also helped facilitate the privatization of many rail transit services.

Despite the contentious nature of decision-making processes affecting investments, it is clear that rail transit continues to have relevance for many people, economies, and geographical settings. The diversity of rail transit services around the world is a testament to their resilience and the power of those who shape them.

Railroad Automation Technology

Railroads have led other forms of transportation in developing automated systems. The most obvious reason for this is the fact that trains operate on tracks, which provide an obvious form of guidance and keep trains from sharing the rails with other transport modes. This factor, along with a culture that supports continuous improvement, have encouraged development of automated train systems, which have been proven successful as parts of urban transit systems and in providing transportation at a very localized level, such as within airports.

In addition, the size, weight, and speed of train operation make it imperative to keep the rails and roadbed in good condition and to maintain sufficient spacing between trains. The enormity of these tasks, as well as the need to detect defects not visible to the naked eye, spurred the development of automated track inspection systems, automatic signal systems, and automatic train control systems.

Automatic Track Inspection

Since the beginning of rail travel, maintaining the quality of the rails and roadbed has been a primary concern. Due to the great weight and high speed of modern trains, the consequences of a failure can be severe, in terms of both economic losses and human injury or loss of life. Regular inspections of the rail and roadbed play an important role in ensuring safe operations. Originally, such inspections were carried out visually, but this process is both time-consuming and unable to identify internal defects. Development of better systems of inspection was partly motivated by information gained from investigations into serious accidents, such as a 1911 derailment in Manchester, New York, in which 29 people were killed and 60 seriously injured. The U.S. Bureau of Safety (now the National Transportation Safety Board) found the cause of the derailment to be a transverse fissure of a rail, a defect that could not be identified visually.

In the United States, the Bureau of Standards began experimenting with magnetic track inspection systems in 1915, and, in 1927, Elmer Sperry built an inspection railcar carrying equipment capable of detecting transverse fissures; it used a magnetic field to record irregularities in the track

A car on the Hartsfield-Jackson Atlanta International Airport (Georgia) Automated People Mover. The driverless train shuttles about 200,000 passengers a day between airport terminals, making it one of the busiest automated systems in the world.

and could identify transverse fissures, although other types of defects passed unnoticed. The next innovation in automated track inspection was the development of ultrasonic methods; ultrasonic rail testing was first used in 1949, and the first all-ultrasonic inspection car, developed for use in the New York City subway system, was completed in 1959.

A rail operator must know the current state of the tracks and roadbed in order to know the speed at which a train can be safely operated over a given route. To address this issue, the U.S. Federal Railroad Administration (FRA) inaugurated the Automated Track Inspection Program (ATIP) over 30 years ago, using geometry cars (specialized railcars that gather information about track alignment, surface conditions, etc.) to inspect about 30,000 miles of track per year, with the goal of increasing annual inspections to 100,000 miles of track.

Besides identifying defects, the ATIP also calculates the maximum safe speed of operation on curved segments of track. Priorities for the ATIP include stretches of track already known to present a safety hazard, routes used to transport hazard

materials, routes that form part of the Strategic Rail Corridor (STRACNET, that is, rail lines considered important to national defense), and passenger routes.

Automated Trains

There are several reasons why automation is particularly suited to railways, perhaps more than other modes of transit: they operate on tracks that provide a built-in guidance system and are used exclusively for trains; they transport large numbers of people over route systems with a limited number of stops; many of their systems, such as signaling and braking, already have a high degree of automation; and trains can operate at very high speeds that are near or beyond the ability of human beings to make judgments in real time. The earliest examples of automatic train operation (ATO) include the London Post Office Railway, which began operation over a 6.5-mile route in 1927, and the 42nd Street Shuttle in the New York City subway network, which was automated from 1959 to 1964.

In the United States, the Urban Mass Transportation Administration (UMTA), now the Federal Transit Administration (FTA), financed the development of fully automated (driverless) railways in several U.S. cities in the 1970s. Several of these cities dropped out of the program, but Miami and Detroit both built automatic railway systems, or people movers, under this program; Jacksonville, Florida, later built a people mover, as well. All three systems are centered on the downtown area of their respective cities. Miami's system, called the Metromover, has the most developed network and is the most successful, with substantial increases in ridership in recent years. In contrast, Detroit's People Mover has been plagued by low ridership and high operating costs, leading to labels such as "the horizontal elevator to nowhere" and "the rich folks' roller coaster."

A few urban subway or light rail systems have fully automated one or more lines, including the Paris Metro (Lines 1 and 14), the Barcelona Metro (Line 9), the Guangzhou Metro (Lines 4 and 5), the Budapest Metro (Line 2), and the Nuremberg Metro (RUBIN or U3 line). However, other systems have seen disadvantages to going to a fully automated, driverless system.

For instance, although some of the London Underground's operations in the United Kingdom are partially automated, when London Mayor Boris Johnson

suggested in May 2012 that the Underground should automate the Docklands Light Railway, the suggestion was met with strong opposition. Most of the objections to fully automated systems have to do with safety, with anecdotal evidence suggesting that human judgment may be superior in unusual circumstances, such as a child on the track or a train out of control and headed for imminent collision.

Fully automated trains are more common at airports, where they may operate within the terminal, as does the Automated People Mover at the Hartsfield-Jackson Atlanta International Airport (Georgia), or between terminals and other outdoor locations (for example, parking lots), as does the AirTrain at Newark Liberty International Airport (New Jersey).

These airport trains exemplify several of the advantages noted above for railway automation in general: they run over relatively short distances and carry large numbers of people to a limited number of destinations. For instance, the Automated People Mover carries about 200,000 passengers daily between terminals in the Atlanta airport, one of the busiest in the world; it is entirely underground and within the secure area of the airport.

Automatic Signaling and Train Control Systems

Because trains operate at high speed and on a limited system of rails, the possibility of a collision is particularly severe. Timetables were developed in part to make operations safer, but systems of signaling were also developed early in the history of the railroads to reduce the probability of collisions. One key to safe operations is block signaling, which divides railway tracks into sections called blocks and uses signals to inform train operators if the block ahead is clear.

Originally, such information was relayed by use of flags and hand signals, later replaced by hand-operated mechanical signals. Today, automated block signaling (ABS) is used in some areas where the frequency of the train service makes it difficult for manual operators to keep up with the traffic. ABS uses electronic methods to determine if a train is present in a block of track; if a train is present, a signal is sent to the preceding block to warn the operator of any train in that block to slow down or stop. Such systems are usually designed so that if they are not functioning properly (for example, if a wire connection is broken), the clear signal will not be given.

In an automatic train control (ATC) system, safeguards are incorporated into the rail system to supplement signal systems and to prevent trains from operating unsafely. For instance, in the New York City subway system, if a train passes a signal in the stop position, or exceeds the permissible speed, the train's brakes are automatically activated. Many passenger rail systems in the United States also use a speed control system, so that if a train exceeds the permitted speed on a line of rail, a signal is triggered in the cab, followed by the triggering of an automatic braking system if the train does not reduce speed.

Railroad Grade Crossings

Railroad grade crossings are the areas where streets, highways, and pathways intersect the rail track at grade or street level. Thus, rail grade crossings facilitate the movement of vehicles, people, and goods over the rail tracks. There are public and private rail grade crossings. Public crossings are open to the traveling public and are under the jurisdiction of and maintained by a public authority. Private crossings are on privately owned highways and pathways.

Rail grade crossings afford a safe, comfortable, and convenient passageway for all users that encourages lawful behavior. There are many different types of crossing material used in practice, including timber, asphalt, concrete, and rubber. The type of crossing material used is primarily determined by the volume of vehicular and nonmotorized traffic that uses the crossing, with additional considerations for drainage, access for maintenance, and pedestrian safety and accessibility.

In addition to rail grade crossings where a roadway and its sidewalks meet the rail tracks, grade crossings are used at or near commuter stations to facilitate the safe movement of boarding and alighting passengers between platforms, as well as of the public at large, to move from one side to the other side of the tracks. Grade crossings also are used at nonmotorist facilities, such as bicycle/walking trails, pedestrian-only facilities, and pedestrian malls.

Design Elements

The geometric design of a rail grade crossing requires consideration of the horizontal and vertical alignment, sight distance, and cross section of both the highway and the railroad. Other important design elements include the selection of an effective crossing surface that will permit smooth passage of vehicular and nonmotorized traffic across the tracks; the provision of signing and pavement or sidewalk marking to give adequate notice of the railroad crossing, and visibility to motorists, nonmotorists, and train operators; and the selection of appropriate warning devices for the crossing environment.

In general, the rail grade crossing design avoids abrupt changes in roadway/sidewalk alignment and grade to meet the railroad. Designing the grade crossing to provide as flat a roadway/sidewalk grade as practical through, and at either side of, the

crossing facilitates the safe passage of vehicular and nonvehicular traffic. Otherwise, the design requirements of grade crossings are similar as those for other roadway intersections.

It is desirable that the intersection angle of the grade crossing relative to the railroad tracks is as close to a right angle as is practical for the location, so that sight distances for both the road/sidewalk user and the train operator are optimized. Moreover, sidewalks and bicycle crossings with the railroad are more sensitive to the skew angle than the main road because of the possibility of bicycle or wheelchair wheels being trapped in the rail flange-way. In addition, obstructions such as vegetation, utility poles, and signs should be located so that the visibility of warning and other informational signs is not diminished.

Planning for Safety

Rail grade crossings, as intersections where trains, vehicles, and nonmotorized users meet, and where the train always has the right of way, are areas of potential conflict, because two or more modes of transportation cannot occupy the same space at the same time. Thus, rail grade crossings present potential conflicts for the movement of motorized and nonmotorized traffic that, unless regulated, would usually lead to catastrophic outcomes for crossing users and train passengers and staff, as well as incurring economic damage to all parties involved.

Improving the safety of rail grade crossings remains a challenging endeavor, especially for nonmotorized users such as cyclists and wheelchair users. This is because pedestrian-crossing incidents occur in different settings requiring the coordination of different stakeholders with context-sensitive solutions. For example, incidents involving violations at rail grade crossings are different than trespassing incidents away from such crossings. Pedestrian crossing incidents at exclusive pedestrian crossings (including rail stations) are different than those occurring at highway-rail grade crossings. Furthermore, incidents in crossings with commuter rail or light rail would require different countermeasures than those occurring in crossings with freight rail.

In general, the safety of grade crossings to vehicles, nonmotorists, and trains is increased with the deployment of crossing traffic control devices such as warning devices (for example, detectable

warnings for users with disabilities, automatic gates, etc.), signs (for example, highly reflective passive warning signs, dynamic signs, second-train-coming electronic warning signs, etc.), channelizing devices (for example, fencing, swing gates, and zigzag gates), as well as pavement markings.

Engineering standards and guidelines for crossing traffic control devices are provided by public and professional organizations. In the United States, for example, such organizations include the U.S. Department of Transportation, state utility commissions, the American Railway Engineering and Maintenance of Way Association, the American Public Transportation Association, and the U.S. Architectural and Transportation Barriers Compliance Board.

Different criteria are used to determine the suitable mix of warning devices and signs that can be deployed at rail grade crossings: (1) collision experience at the crossing; (2) frequency of inclement weather; (3) vehicular and nonmotorized volumes; (4) train speeds, number of trains, and railroad-traffic patterns; (5) surrounding land uses; (6) sight distance for approaching vehicles and nonmotorists; (7) skew angle of the crossing relative to the railroad tracks; (8) presence of multiple tracks; (9) vicinity to a station or platform; and (10) installation and maintenance costs. Engineering studies usually determine the types of warning devices that are necessary at each crossing location.

In order to improve safety at rail grade crossings, certain activities need to be routinely performed. First is a continually updated data inventory that includes the location of the crossing, traffic and train volumes, and physical elements and collision history of the crossing; second is a process for analyzing available data to identify hazardous crossing locations on the basis of collision experience or collision potential; third is a process for implementing and evaluating safety improvements; and fourth is education and enforcement campaigns for reducing user violations at rail grade crossings. Additional actions may be necessary in grade crossings with high-speed rail operations.

Interesting new developments in the area of cooperative Intelligent Transportation Systems (ITS) may soon bring to bear applications that could dramatically affect safety for users in grade crossings. Vehicle-to-vehicle (V2V), vehicle-to-infrastructure (V2I), and vehicle-to-consumer devices (V2D) are

being developed to deliver more safety mobility benefits. Drivers, pedestrians, and nonmotorized users, in general, at rail grade crossings will be able to receive personalized advance warning of incoming trains in time to avoid injuries and fatalities.

Risk Management

A consistent approach for managing the risk at rail grade crossings would assure (1) the uniformity and continuity of data collection programs, and administration of related databases, on all such crossings; (2) the analysis of risks at such crossings; (3) the prioritization of crossing upgrades; (4) the introduction of suitable risk controls; and (5) the assessment of cost-effectiveness of such measures.

Moreover, a program of risk management that includes expertise in the areas of engineering, education, enforcement, enabling, and evaluation (or “five Es”) could increase safety at rail grade crossings. This is because of the following:

- Engineering solutions can integrate the deployment of lights, horns, barriers, communications, and signs in innovative ways.
- Education initiatives can increase public awareness of the dangers of crossings, and educate pedestrians, road vehicle drivers, and other users how to use them correctly.
- Enforcement makes use of laws to prosecute those who endanger themselves or others by misuse of crossings.
- Enabling provides resources through people, procedures, and systems to allow activities in the other “Es” to be effective.
- Evaluation encourages organizations to set a baseline before embarking on new initiatives so that the before and after can be properly compared.

Railroad Industry, Economics of

A railroad is a form of transportation infrastructure that enables locomotives to drive various configurations of cargo and passenger cars from one node in the system of tracks to another. Railroads are customarily laid between two endpoints, and locomotives run between them—in two directions simultaneously after dual-track replaced single-track systems—passing through various stations along the way where passengers and cargo can be added or subtracted.

Because the locomotives and rolling stock roll along the parallel rails, changing directions is only possible at designated switching points, which are now operated electronically.

Infrastructure is a form of enabling technology that provides opportunities for people to use it for their own purposes, whether these are commercial or noncommercial in nature. Although such people will contribute some support to the railroad network through buying tickets or paying fees, they will by definition derive more benefit from the journey than the fare required; otherwise, they will not pay it, at least according to the theory of rational choice based in microeconomics.

Consequently, when seeking to quantify the benefit of a railroad, it is important to use a suitable multiplier figure because \$1 of investment will return more than \$1 of return. This is based on the assumption that the railroad is properly planned and constructed between nodes for which there is a demand for services.

Railroads cannot operate in isolation but rely on accompanying forms of infrastructure, including fuel supplies, repair facilities, stations with facilities for passengers, and equipment for loading and unloading cargo. It is apparent that providing all of these facilities is a large-scale undertaking that requires a substantial organization to take care of all of it.

In the case of India, which is perhaps the most notable example of a universal state-managed system, the organization managing the railways is enormous in scope and requires considerable amounts of finance, housing for employees, human resource support, and all the other functions required for a corporation of very large size. The organization has become a significant feature of the contemporary society and economy, and, potentially, within politics as well.

Construction of railroads in the developed world began in the 19th century and spread and intensified in the 20th century. Railroad building was a symbol of modernization and of nation-building in those countries, in addition to being an important tool for economic development. In a country such as the United States, where large low-population-density areas exist between major urban centers, the ability to attract a railroad through a rural community could mean the difference between whether that community was sustainable or not. People and businesses from neighboring communities would be likely to move to where the railroad station was located, so as to reduce transaction costs and because more customers were likely to congregate there. This is an example of how trade diversion can exist alongside trade creation, depending on the location of infrastructure.

Outside the developed world, the spread of the railroad in a country did not always elicit the same positive feeling, because it was often a sign of the intensification of colonization or the linking of local communities to distant markets over which local people can have little control. In Imperial China, for example, a fiercely contested debate took place before it was decided to permit foreign capital to enter the country to build railroads, and thus to connect Chinese territory and customs with the emerging international capitalist order.

It is not surprising that people were concerned, given the incredible level of corruption and graft that accompanied the construction of American

railroads, for example, not to mention the inhumane treatment of the thousands of Chinese laborers working on that construction.

In the colony of Burma (now Myanmar), the railroad, seen as a representative of the British Empire, was used as a means of connecting the gem mines of the interior with the coastal colonial capital of Rangoon, from which the products of Burmese labor were extracted for the benefit of a foreign crown.

Elements of Railroads and Ownership

In the United States, railroad construction was first driven by private investors seeing to make a profit by linking lively destinations, driving down costs through repressive workplace relations, and attempting to obtain concessions and subsidies from state and local government agencies. The violence with which the Pullman railroad strike of 1894 was crushed is viewed with astonishment by people of the current day.

By contrast, European railroad systems were mostly built by state-owned organizations that were mandated to take account of the need to unite distant communities with the center in the interest of the nation. Such systems placed railroads themselves, locomotives and rolling stock, and station facilities and maintenance under the control of a single organization. However, as facilities became more extensive and complex in nearly all the countries where they existed, it also became evident that differential management systems might be preferential.

Initially private, most of the railroads in the United States rolled into the public sector, although—turning full circle—the desire for privatization has been growing in intensity since the late 1970s. While this movement has involved some railroads, many (but not all) have become loss-making ventures lacking sufficient income. Consequently, various attempts have been made to divide railroads overall into component parts, including the distinction between maintenance of track and rolling stock, management of station facilities and concessions for retail opportunities within the station concourse. The results of privatization have, as ever, been mixed.

Private corporations have been willing to take on contracts in areas with high demand for services and have made large profits in some cases, such as some privatization projects in the United Kingdom. However, the public service aspect of railroad

provision is incompatible with profit seeking, and so remote areas have not been popular for privatization. Further, the separation of services by rail and stock rather than on a geographic basis, as has more successfully been managed in Japan, has contributed to a situation in which underinvestment has occurred and performance suffered as a result.

Station facilities exhibit a similar pattern, as some services have been subcontracted and have in some cases been made into profitable commercial activities. This has not always been a popular practice, although it has contributed to the convenience of contemporary urban living.

Railroad's Role in the Economic System

When seeking to calculate the rate of return from railroad investment, there are several approaches that can be used. These include the amount of passenger fares or cargo fees received per dollar of investment in the project, a calculation that would be appropriately adjusted for amortization of capital goods and the cost of capital. A more contemporary approach would also seek to incorporate the social and environmental impact of railroad project construction as part of the triple bottom line approach.

However, historically railroads have had a particularly important place in the development of economic thought, especially in the United States. In the first place, railroads were considered to be an important means of spreading economic growth throughout the continent. In other words, it was established that building a railroad promoted additional economic growth that would not otherwise have occurred at its various nodes, which means a multiplier effect is occurring and this should be considered a positive externality.

Further, railroads and their operation were used as direct inputs in the development of understanding of cost-estimate functions and, later, multiproduct pricing theory. The fact that railroads crossed multiple state borders and that data collection in the United States, being the best available, meant that this study was seminal for the understanding of uneven economic development and the impact of deregulation, which was handled differently on a state-by-state basis.

However, the role of railroads has become less relevant as alternative modes of transportation have been developed and as more value has become

attached to services and knowledge-based products that do not require physical transportation.

Railroads, in common with other forms of transportation, also have other forms of positive externality resulting from their existence. This includes the promotion of national identity, which was especially relevant during the period of modernizing nation-building. This is a process that remains important in countries with significantly different ethnic or linguistic groups.

In countries with land borders, railroads have also contributed significantly to economic growth on both sides of those borders by supplementing the seaports, which had previously been the principal means of exporting goods. Railroads also promote social stability and harmony by giving the means to people to travel for social and leisure purposes at comparatively low cost. Mass transit systems are preferable to personal automobiles for this reason, as well as the beneficial environmental implications.

Railroads, Freight

Freight trains are those trains that transport freight rather than passengers; they consist of a series of freight cars pulled by a locomotive or series of locomotives. Freight or cargo consists of goods transported for commercial purposes, and today they are primarily shipped in standardized containers that have been optimized for intermodal transport—meaning they are easily transferred from one mode of transport to another, such as from a cargo plane to a train, without need of repackaging.

When it is practical, rail transport is a cheaper and more energy-efficient means of freight transport than trucking, and the gains increase with distance. For shorter distances, the railways' lack of flexibility is a disadvantage. Intermodal transport is more and more common, with freight railroads forming an important component of the overall freight transport story. In addition to carrying ordinary cargo, freight trains are critical to the transport of steel, wood, and coal. Because these industries predate or grew up alongside the advent of the railways, their production facilities and the destinations of their goods are located along railway routes.

The use of standardized containers is called containerization. The containers, called shipping, freight, or intermodal containers in formal literature, and often just "boxes" in the industry, are reusable and come in standard sizes. Most are of a height and width appropriate for transport by truck or train and come in lengths of 20, 40, 45, or 53 feet. Inside the container, freight is kept steady with lashes, synthetic webbing, and steel straps, and airbags are inflated to fill empty space to prevent freight from shifting during loading, unloading, and transport. Containers stack up and next to each other and lock in place, ensuring safe cargo so long as the freight inside has been properly packed.

Containerization is the bedrock of the modern shipping industry, allowing for maximum packing efficiency of freight transport vehicles (with no unused space left over because of containers of incompatible sizes) while significantly reducing the amount of time it takes to load a freight car. Most major cities and ports have a container terminal, often near an airport or seaport, where freight is received and transferred to the vehicles that will bring it to its final destination.

One of the common types of train cars used for freight is the flat car, an open car consisting of a flat deck with some kind of mechanism on the sides for securing loads, which can range from simple tie-down points to sliding assemblies used to hold machinery in place. Flatcars are used for freight too large or unwieldy for enclosed cars, and in addition to the typical flatcar design, come in a variety of specialized freight designs, from “sky box” flatcars for transporting aircraft parts, bulkhead and center-beam flatcars that have open tops but sturdy walls to keep cargo inside, even flatcars used to transport circus equipment.

Containerization has popularized the use of well cars, which are railroad cars designed to hold containers. Their name comes from the depression close to the rails that allows the container to be carried lower than on a standard flatcar. This allows loaders to stack two containers one on top of the other, with a center of gravity low enough that the load is still stable. Well cars are a distinctly American freight car, since European rails tend to have less manageable overhead clearances, often due to electrification. Another flatcar design that accommodates containers is the spine car, which uses lateral arms to support them.

The most familiar freight car is likely the boxcar, an enclosed car used for general freight, with side doors and adjustable bulkheads. They are the most versatile car and were originally loaded manually, but today forklifts and other mechanical means are used for speedier and less dangerous loading. Transporting livestock in boxcars was standard until the late 19th century, but modified boxcars called stock cars are used today, which are better able to deal with the climate.

Stock cars have louvered sides for ventilation, and when transporting smaller animals like pigs or sheep, they are often separated into two or three levels. Specialized stock cars are even used to transport live fish, and have been since 1874, when 35,000 shad were transported to the Sacramento River to stock it. “Fish cars” were a popular novelty attraction at the turn of the century. Because of the relatively small size of chickens and similar birds, they were often transported in stock cars called wheeled henhouses, which were built with mesh walls and multiple levels of individual coops with food and water dispensers. Such cars required an attendant to travel with the birds to keep them fed

A freight train carries a series of relatively small cargo containers on flatcars near the village of Dombås, Norway. Freight is usually stabilized inside containers with lashes, synthetic webbing, steel straps, or airbags that are inflated to fill empty space.

and watered. Live poultry shipping is not quite as common now that cargo flights have become more common and affordable, and changes in the poultry industry have reduced the need.

Boxcars were also used to transport automobiles until the 1960s, with development of the autorack. An autorack is a specialized freight car that transports cars and pickup trucks from factories to distributors, often with a double-decker design in order to meet demand cost-efficiently.

Another specialized freight car is the gondola, which looks much like a boxcar from the side except for having low walls and an open top. Gondolas are named for the flat boats used to carry coal down rivers in the 19th century—themselves named for the more romantic boats of Venice. The freight cars used to carry coal have outlived the boats, though they are used for a number of other purposes now, similarly centered around dense cargo like minerals or metals. Metal coils, especially steel, are usually carried in coil steel cars, which replaced gondolas

for this purpose. A coil steel car has a series of troughs that cradle the coils, and usually a hood to cover the car after loading.

Today, there are over 500 common-carrier freight railroads operating in the United States. There are eight Class I railroads, the railroads with annual carrier operating revenues of at least \$250 million, adjusted for inflation, according to the Railroad Freight Price Index: Amtrak, BNSF Railway, Canadian National Railway, Canadian Pacific Railway, CSX Transportation, Norfolk Southern Railway, Union Pacific, and the Kansas City Southern Railway. Of these, only Amtrak is not a traditional freight railroad, focusing almost entirely on passenger service, though it does handle freight transport of packages, human remains, and a number of other small categories, and its tracks are used by freight transporters.

Railroads, Passenger

Since 1869, when the Transcontinental Railroad was completed, a national rail service has played a key role in the United States' economic and transportation infrastructure. Through the mid-1940s, private railroads continued to play a dominant role in intercity passenger travel on a national scale. Plying the tracks of the freight rail industry, private-rail

passenger service between America's growing urban centers faced little competition from other modes of transportation.

Following World War II, however, as the economy boomed and passenger miles-traveled dramatically increased, automobile and air modes of transportation dominated government transportation funding. Beginning in the 1950s, highway and air transportation modes received the majority of government transportation funding. Even today, passenger rail has no dedicated funding source similar to the Highway Trust Fund, established in 1956 to pay for the interstate highway system and other roads, and the Airport and Airway Trust Fund, created in 1970 to increase capacity in the rapidly growing air transportation market.

Passenger rail, operating then within the private sector, was provided no such programmed government subsidy. Faced with the emerging dominance of the automobile and mass-market air travel in the early 1960s, private passenger railroads began to lose money on their passenger routes and, by 1970, most had gone out of business.

Amtrak and Early Interest in High-Speed Rail

Congressional interest in high-speed passenger rail can be traced back to 1965 with the passage of the High Speed Ground Transportation (HSGT) Act, which began a federal effort to develop and demonstrate "contemporary and advanced HSGT technologies." These efforts led to significant planning for, capital investments in, and service improvements in the Northeast Corridor linking Washington, D.C., and Boston, Massachusetts.

In 1970, Congress created the National Railroad Passenger Corporation—popularly known as Amtrak—as a private, for-profit, federally sponsored corporation to preserve intercity passenger service across the nation. In exchange for relieving private rail companies of their passenger responsibilities and associated financial losses, Amtrak was granted access to freight railroad companies' track, as well as travel priority over freight trains.

However, outside of the Northeast Corridor and a few states that invested in modernizing passenger rail routes within their jurisdictions, there was limited investment in the U.S. passenger rail system infrastructure or capacity. Regular federal appropriations were designated for Amtrak's capital

needs and to cover operating deficits, and long-term infrastructure and investment planning was subsequently difficult.

The 1980s brought forth several studies of potential, “emerging,” high-speed passenger rail corridors and the emergence of states as leading drivers behind the planning for and development of high-speed rail services. Several states formed public-private partnerships to build and operate intercity high-speed rail systems. Since the 1980s, however, in the face of the need for continuing federal subsidies, Amtrak has continually faced political challenges to its survival. In spite of the fact that, since 1997, ridership on Amtrak has grown faster than all other major modes of travel, after a \$700 million subsidy in 2005, it again faced elimination of its operating subsidies in the 2006 administration budget.

A New Vision for Passenger Rail

In early 2009, President Barack Obama’s administration proposed “[a] combination of express and regional high-speed corridors, evolving from upgraded, reliable intercity passenger rail service.” It proposed a “down payment” of \$8 billion in American Recovery and Reinvestment Act of 2009 funding and an additional \$2 billion in annual appropriations to be allocated to completing individual “ready to go” passenger rail projects, and entering into cooperative agreements with states, or groups of states, to develop entire portions of corridors having completed corridor plans and environmental documentation.

Immediately following this announcement, the Federal Railroad Administration (FRA) published “The High-Speed Rail Strategic Plan” and launched the High-Speed Intercity Passenger Rail Program (HSIPR) to make strategic investments in a network of passenger-rail corridors across the country. Objectives of HSIPR include the following:

- Build new high-speed corridors that expand and improve passenger transportation in their service areas
- Upgrade existing intercity passenger rail corridors to improve reliability, speed, and service frequency
- Lay the groundwork for future high-speed rail services through corridor and state planning efforts

Passenger Rail Investment and Improvement Act of 2008

Recognizing that high-speed and intercity passenger rail development would be a critical element of American economic growth and competitiveness, Congress passed significant legislation creating rail planning, development, and safety programs. The fundamental notion behind this new legislation was that passenger rail should be prioritized in federal and state planning and funding processes, alongside other transportation modes, in order to provide travelers with transportation alternatives over differing geographic scales.

The fiscal year 2008 Appropriations Act established a new intercity passenger rail state grant program (Capital Assistance to States-Intercity Passenger Rail Service) that provided \$30 million in competitively allocated funding to states that was contingent on a 50 percent nonfederal match. Up to 10 percent of the grant could be used for rail corridor planning projects.

The Rail Safety Improvement Act of 2008 (RSIA) reauthorized and augmented the FRA’s safety programs. Notably, the act required that all Class I railroad carriers and all regularly provided intercity or commuter rail passenger services implement positive train control systems no later than 2015. Positive train control systems comprise onboard automation to ensure train separation or collision avoidance, line speed enforcement, temporary speed restrictions, and rail worker wayside safety. This requirement provides the necessary rail traffic control to accommodate passenger trains traveling at significantly higher speeds than are presently achievable on shared infrastructure.

Finally, aside from reauthorizing Amtrak, the Passenger Rail Investment and Improvement Act of 2008 (PRIIA) revamped the federal-state partnership by requiring that Amtrak and the states develop a uniform cost structure for high-speed and short-distance (750 miles or less) routes outside the Northeast Corridor. It also established new high-speed and intercity passenger rail capital-improvement grant programs.

Under the Intercity Passenger Rail Service Corridor Capital Assistance (Section 301) program, states (including the District of Columbia), groups of states, interstate compacts, and state-established public intercity passenger rail agencies may apply for grants to pay for up to 80 percent of capital

projects designed to improve intercity passenger rail service. Importantly, eligible projects must be contained in a State Rail Plan.

The High-Speed Rail Corridor Development (Section 501) program is similar to Section 301 but is restricted to projects intended to develop federally designated high-speed rail corridors. Amtrak is also eligible to apply for this funding. Congestion Grants (Section 302) authorizes grants to states or to Amtrak (in cooperation with states) for financing of up to 80 percent of the capital costs of facilities, infrastructure, and equipment for high-priority rail corridor projects necessary to reduce congestion or facilitate intercity passenger rail ridership growth. Finally, Public-Private High-Speed Rail Concepts (Section 502) encourages public-private rail system development projects along federally designated high-speed rail corridors or Amtrak's Northeast Corridor.

PRIIA requires that states develop a State Rail Plan in order to be eligible for grant funding under these programs. It also requires that the U.S. Department of Transportation (USDOT) develop a National Rail Plan that is consistent with approved State Rail Plans. According to the High-Speed Rail Strategic Plan, the National Rail Plan "outlines national rail policies and priorities to promote an integrated, cohesive, efficient, and optimized rail system for the movement of goods and people."

National Rail Plan

Responding to the PRIIA requirement, the FRA in 2009 published a "Preliminary National Rail Plan" outlining the approach to be used for developing the National Rail Plan and policies to improve the U.S. transportation system consistent with the USDOT's overall strategic goals of improving safety; fostering livable communities; increasing the nation's economic competitiveness; and promoting sustainable, integrated, multimodal transportation. It recognizes the importance of the national rail system to the economic vitality of the United States, and the potential for passenger rail to contribute significantly to future growth. At the same time, though, it recognizes that passenger rail is dependent on privately owned infrastructure and that the private sector will play an important role in the success of any future passenger rail development.

Through the identification of projects of national significance, the National Rail Plan will be focused on increasing passenger and freight rail performance

by improving national transportation system performance. In order for this to be realized, rail must be better integrated with other modes of transportation to form a more complementary transportation system. The National Rail Plan proposes strategic investments in a high-speed intercity passenger rail network yielding "tangible benefits to intercity rail infrastructure, equipment, performance, and intermodal connections." In a 2010 progress report, it refines its vision by proposing a network of high-speed passenger rail corridors tiered according to geography and train speed.

The backbone of the national passenger rails system, core express corridors would connect large urban areas up to 500 miles apart with trains traveling 125 miles per hour (mph) to 250 mph with travel times ranging from two to three hours. These routes would be run on dedicated, electrified, publicly owned tracks. Operating between midsized urban areas, regional corridors would provide frequent 90-mph to 125-mph service on a mix of dedicated and shared (with freight rail) track. These routes could connect core express corridors. Emerging/feeder routes would connect regional urban areas at speeds up to 90 mph. These routes could connect to both core express and/or regional corridors, providing less densely populated or more distant areas with access to the national transportation network. As of this writing, the National Rail Plan has not been finalized.

State Rail Plans

Perhaps the most important requirement of PRIIA is the requirement that states develop formal plans that include passenger rail projects seeking capital project funding under the act. In 2012, the FRA issued process and content guidance to states for the development or update of their rail plans, emphasizing the requirement that any capital projects funded under Sections 301, 302, or 501 must be contained in the state rail plans of the applicant states.

PRIIA defines the following four primary responsibilities for states in rail planning:

- Establishing a state authority to develop the State Rail Plan to establish priorities and implementation strategies and serve as the basis for federal and state rail investment
- Coordinating with statewide and metropolitan area transportation planning agencies

- Involving public and private stakeholders—including all freight and passenger rail carriers, transit authorities, and other entities interested in improving statewide rail services and multimodal integration—in the plan development process
- Coordinating with neighboring states on common corridors

It also outlines the following role for the federal government in state rail plans:

- Establishing minimum content requirements and a recommended format for plan preparation, update, and submission
- Offering cooperative funding agreements for the completion of state rail plans and other planning activities

- Coordinating state rail plans with national and multistate rail planning efforts
- Developing analytic tools that can be used by states and other stakeholders to develop state rail plans or other planning documents

All of the contiguous 48 states and Alaska have drafted state rail plans.

A Bright Future for U.S. Passenger Rail?

The initial PRIIA grant programs were enormously successful, demonstrating not only a renaissance in interest in passenger rail in the United States but also a willingness of states to work with each other and with the federal government and private rail companies toward the expansion and improvement of intercity passenger rail. The federal

The Rajdhani Express was introduced in 1969 to provide fast connections from New Delhi to the capital cities of various states in India. Passenger train service in India has since expanded rapidly, especially over the past decade. The West Central Railway became operational in 2004 and is one of 17 new railway zones of Indian Railways, with its headquarters at Jabalpur.

government received \$102 billion in preapplications and \$55 billion in final applications for the \$8 billion available funding from ARRA. In addition to funding 38 projects across 31 states, the federal government succeeded in creating a long pipeline of passenger-rail projects awaiting future funding opportunities.

Many major projects were undertaken under PRIIA funding, including a nearly \$1 billion investment to upgrade some of the most heavily utilized segments of the Northeast Corridor, Amtrak's most successful. Notable, as well as controversial, was the nearly \$4 billion to fund environmental and engineering studies for the first segment of a 220-mph high-speed rail system through the Central Valley of California planned to link Los Angeles and San Francisco.

Following this success, the second Obama administration called for a six-year, \$53 billion spending plan. Congressional funding of this continuing initiative is still uncertain as of this writing. Furthermore, no source of funding outside year-to-year congressional budget allocations has been identified to secure Amtrak's long-term survival or to enable it to make the sort of investment decisions necessary to realize its full future potential.

Rails-to-Trails Programs

There are tens of thousands of miles of public recreational trails in the United States, with the number increasing annually. The wide variety of trail uses include remote hiking and camping, snowmobiling in northern forests, and bicycle commuting in the nation's dense metropolitan areas. Rich hierarchical networks of trails have emerged over the past five decades through federally facilitated public, private, and not-for-profit (NFP) collaborations. "Rails-to-trail"—the reuse and multiuse of abandoned railroad corridors—is an increasingly important, specialized component of this process.

Following World War II, the nation faced many challenges in its transformation to a peacetime economy. One of these was the escalating gap between the supply and demand for outdoor recreation. The gap was a result of the steep population growth during the baby boom, rapidly increasing mobility from auto ownership, the construction of the interstate highway system, reduction in the workweek, increased disposable income, and the accelerating open-space loss from suburban sprawl.

In 1958, Congress established the Outdoor Recreation Resources Review Commission (ORRRC) to conduct a nationwide inventory and analysis of resources and opportunities, with trend forecasts for 1976 and 2000. In addition to federal land management agencies, all states participated. The ORRRC analysis was an innovative use of multidiscipline, quantitative social science. It legitimized outdoor recreation as an important topic in legislative and administrative decision making and a new field of academic study. ORRRC recommendations included the following: creating a systematic resource classification system for facility planning

and management; improving collaboration between federal, state, and local governments, with “citizens and private enterprise continuing to play the most important role;” and the need for innovative funding approaches.

In 1965, Congress passed the Land and Water Conservation Fund Act (LWCF). This legislation allowed a portion of the federal income from offshore oil and gas leasing to be used for statewide, comprehensive outdoor-recreation planning. Based on these plans and a state-established system for project prioritization, states could apply for 50 percent matching funds for state and local governments to acquire land rights, and undertake conservation-related restoration and development projects, including trails.

In 1966, the Bureau of Outdoor Recreation (BOR) released *Trails for America*, a nontechnical report advocating a comprehensive national-state-local program. This became the basis for the National Trail System Act of 1968 (NTSA), which authorized a National Trails System (NTS) with three categories: scenic, recreation (“reasonably accessible to urban areas”), and connecting and side trails. A fourth category, historic, was added in 1978. NTSA also encouraged states to include complementary statewide, regional, and local trails in their plans and applications for LWCF funding, thus, over time, generating integrated systems. Today, NTS trails exceed 50,000 miles.

Trail planners in this period looked closely at joint-use opportunities involving existing utility corridors, such as railroads, pipelines, and electric transmission lines. These presented major challenges because of their private corporate ownership, as well as associated safety and liability issues. Although utility corridors were growing, construction of the interstate highway system had significant negative economic impacts on the nation’s railroads, as trucking rapidly captured freight market share.

Railroads, with extensive public assistance, had played a major role in the economic development of the country from the mid-1850s through World War II. Private rail corporations acquired extensive networks of real property interests by multiple means. Some private lands were purchased outright, either in fee simple (full title) or right-of-way (ROW), which provides private corporate access for construction, operations, and maintenance. In much of the Midwest and west, the federal government had

Part of Atlanta, Georgia’s, BeltLine Trail undergoes construction in 2012. This rail-based trail, which will eventually encircle the city, is part of a comprehensive greenway program that includes parks, transit, and neighborhood redevelopment.

originally acquired land by treaty or war. Various programs, such as homesteading, were undertaken to transfer title to the private sector.

Railroads were critical for this transformation. As incentive, they were frequently granted fee-simple title or an ROW for their lines through public lands. In some regions, they were also given title to adjacent land for development or sale. ROWs were granted for routes across federal lands, such as national forests, and into national parks, where rail corporations were encouraged to build and operate tourist lodges. Rail lines were essential for mining on federal lands, too. U.S. railroad mileage peaked in 1900 at over 250,000 miles; today, the total is under 100,000 miles.

By the 1970s, there were numerous railroad bankruptcies and increasing pressure by rail corporations to abandon unprofitable routes. The Railroad Revitalization and Regulatory Reform Act of 1976

(4Rs) was part of a reform initiative to encourage private enterprise through regulatory reduction. The 4Rs eliminated the Interstate Commerce Commission and created the Surface Transportation Board (STB) within the U.S. Department of Transportation (USDOT) to regulate railroads, including abandonments, for which rail corporations must apply. The STB decides those requests based solely on economic impact, weighing the loss of service to local communities and businesses versus the ability of the rail corporation to continue profitable operation and grow services in other geographic sectors of its system.

Rails-to-Trails

If abandonment is approved, STB regulations provide opportunities to transform all or part of the line to public trail use. "Rail banking" is an option where the line is on an ROW and the rail corporation has an interest in potentially reactivating the line at some future date, for the reopening of a mine, for example. If an agreement is reached between the corporation and trail reuse intervener, a government agency or state-approved NFP, the corporation may salvage rails and ties and gain tax advantages through charitable deductions and subsequent reductions in property taxes. The trail ROW receiver assumes liability and structural maintenance responsibilities. The rail corporation retains "first right of refusal" to reacquire the ROW if it comes up for sale at a future date.

Where the railroad holds fee simple ownership and is not interested in banking, there is an alternative approach. Following the abandonment approval, trail conversion interveners have 180 days to negotiate with the corporation for title transfer. If no trail agreement is reached, the property can be sold on the open market for another use.

The 4Rs regulatory opportunity window for rail-to-trail conversion was complicated by the need for careful monitoring of the railroad regulatory abandonment proceedings in Washington, D.C.; by shortfalls of funds; and by multiyear waiting lists for the state-approved LWCF funding. By the 1980s, under STB's 4Rs, up to 10,000 miles of rail were being abandoned each year, little of which was being converted to trail use.

In 1986, the Rails-to-Trails Conservancy (RTC) was created in Washington, D.C., to focus on this specific latent opportunity. The RTC, working with

other environmental groups, has been particularly effective in influencing federal legislation. The 1988 National Trail System Improvement Act includes a section under the heading "Abandoned Railroad Grants; Retention of Rights" that closes a significant loophole. When the STB approves abandonment, if the route is an ROW on federal land, the ROW automatically reverts to federal ownership. Where this route occurs outside an active federal land management unit, such as a national forest, it can be transferred directly to an approved trail agency or NFP. Where trail use is not feasible, the federal property rights may be sold, with the proceeds going to the LWCF.

A major funding success was achieved in the drafting of the Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA). This law created two new programs operated by the Federal Highway Administration (FHWA). The Transportation Enhancement (TE) Program was allocated 10 percent of all surface transportation funds, to be utilized for 12 types of construction-only projects including pedestrian and bicycle facilities, and "conversion of abandoned railway corridors into trails." TE funds are allocated to state transportation departments.

In metropolitan areas, trail projects proceed through the Metropolitan Planning Organization's Transportation Improvement Program (TIP). In nonmetropolitan areas, they are approved by the state TIP. Approximately 8 percent of TE funds have been used for rail trails. ISTEA also created the Recreational Trails Program (RTP). This sends Federal-Aid Highway Program funds collected from non-highway-use fuel taxes, such as from snowmobiles, back to the states.

Paralleling the LCWF, most states administer RTP funds through a park or natural resources agency with a citizen trail advisory committee. A minimum of 30 percent of RTP-funded projects must allow motorized uses. TE funding has become more highly controversial in each subsequent transportation act. This is because Congress has not increased the federal fuel tax to keep pace with the rapidly rising costs of maintaining or replacing the aging interstate highway system.

For three decades, the RTC-led rails-to-trails movement has been a very successful component of larger trail and greenway initiatives. There are now over 20,000 miles of rails-to-trails completed, with 9,000 miles in process. In 2001, President George

W. Bush issued Executive Order 13195, "Trails for America in the 21st Century." It created the Federal Interagency Council on Trails to coordinate all federally assisted trail programs.

The FHWA has established a Trails and Enhancement unit in the Office of Planning, Environment, and Realty to facilitate federal rails-to-trails-related programs and the 50 RTP state programs. It provides a central clearing house for program data, technical assistance information, and educational resources. The FHWA's planning and design guidelines differentiates between "rail trails," which are in abandoned rail corridors, and "rails-with-trails" in which the trail is adjacent to an active rail line. Rail-based trails play a significant role in achieving the goals of the early ORRRC report. Examples range from Nebraska's 319-mile "Cowboy Trail" rail-bank corridor to the evolving "Atlanta BeltLine" trail, which will eventually circle the city. The latter project is part of a comprehensive greenway program that includes parks, transit, and neighborhood redevelopment.

Railroads expanded rapidly throughout the world in the 19th and 20th centuries. Today, the rails-to-trails movement is under way in many countries in addition to the United States. Each is evolving a unique set of institutional, economic, and collaborative approaches to this important recreational and environmental opportunity arena.

Recreational Travel

Over the last 100 years, a general rise in individual wealth, improvement in living standards, and related increase in leisure time has come with an associated rise in travel for recreational purposes. Such travel can be divided into two categories: international and domestic. The United Nations World Tourism Organization (UNWTO) reports that international arrivals worldwide have more than doubled since 1990, rising to 940 million in 2010. The World Travel and Tourism Council (WTTC) indicates that these figures do not take into account domestic tourism, which is estimated to generate up to 10 times more arrivals than international tourism. The U.S. Travel Association (USTA) reported that direct spending on leisure travel by domestic and international travelers totaled \$564 billion in 2011.

Travel is fundamental to accessing recreation opportunities. Therefore, tourism would not exist without transportation; it provides the connectivity between home origin and leisure activity destination. Recreational travel involves a household's discretionary budget. This means that there are a number of factors that may influence the decision to make a trip. Some of these are the competing demands on the time available to travel, the perceived value of the journey, and the availability of satisfactory services to meet the travelers' needs. In addition, although people's potential leisure time may have increased, there may also be limitations on its availability because of barriers such as employment commitments and restrictive vacation windows.

Recent research on European Union leisure travel has provided valuable insights into the factors that can influence recreational travel choices. The research found that people are more likely to make trips within their own country, and that these journeys tend to be by automobile. A report on global travel trends, meanwhile, found that people are taking shorter breaks, flying rather than taking their car when they travel internationally, and that Europeans are increasingly choosing long-haul destinations, such as the Americas and the Asia Pacific region.

Individual traveler demographics, travel companion arrangements, traveler preferences and perceptions, and destination characteristics are also found to be important to the leisure travel choices made.

As noted above, an important aspect of individual sociodemographics is available disposable income. For example, in the United States and United Kingdom (UK), as the recession of recent years took hold, household incomes and budgets were affected, spawning a greater propensity for vacationing at home, leading to the coining of the term *staycation*.

Exploring motivations for recreational travel reveals numerous reasons for deciding to make a trip. For example, looking at domestic travel and taking the United States as an illustration, the USTA reports that in 2011 the top leisure travel activities for domestic travelers were (1) visiting relatives, (2) shopping, (3) visiting friends, (4) fine dining, and (5) beaches.

In terms of international travel, the UNWTO reports on worldwide arrivals by purpose of visit. This data indicate that the main activity categories were, respectively, leisure/recreation/holidays and visiting friends and relatives/health/religion. Visiting friends and relatives, according to the WTTC, represents up to one-third of all arrivals for some large developed markets, pointing to the importance of maintaining cultural and ethnic links when traveling internationally during leisure time.

Recent research has explored the relational nature of recreational travel further. One research team highlights the complexity of leisure travel, indicating that it is dependent on a combination of other people's participation, characteristics of the destination, and, at the same time, linkages between activities and people's social networks.

Social and Economic Significance

The social and economic significance of recreational travel is manifold. On the positive side, it supports local jobs, justifies investment in infrastructure, and promotes cultural asset preservation. Negatively, it contributes to traffic congestion and other environmental degradation effects, can generate economic benefits that are not reinvested locally (for example, all-inclusive resorts), and can portray the population of the host location in purely subservient roles.

Looking at the transportation-related impacts of recreational travel in more detail, the positive effects of infrastructure development—such as road improvements, airport development, and increased transport connectivity structures—are not only benefits to inbound tourists but also to the wider

local community. However, such improvements come at a price, which is usually borne by the government of the host community.

In addition, large-scale transportation projects can involve extensive land acquisition (including compulsory purchase of local homes), resulting in severing of communities, and broad environmental effects (such as increased noise, revision of water and sewerage routings, and other impacts on natural resources).

It also should be noted that the tendency for domestic leisure trips to be made by car has implications for sustainability. For example, in the UK, there has been an increasing demand for leisure trips that are mainly made by car. Given the concern about environmental impacts of automobile use, there is an imperative for visitor attractions to encourage modal shift to more sustainable options.

Turning to the supply of recreational travel services, the distribution of travel information and booking processes has been undergoing considerable change in the past couple of decades. In the past, travel agents and airline distribution systems were the dominant channels of sale in the area of leisure travel products and services. As Internet access has become almost ubiquitous, the ways in which people access information and then go on to book leisure travel has also evolved to reflect the use of new media.

Not only do an increasing number of people book their leisure travel directly on the Web, but research also suggests that people are tending to base leisure travel decisions more and more on what friends say on social media or even what strangers post in reviews on various travel sites. It may be that the trend toward decision making that involves others' experiences relates to an inclination to seeking more authentic and individualized experiences. Against this background, the cookie-cutter, packaged holiday may start to become a less viable solution for many, and suppliers will need to adapt to a much more tailored approach to satisfying traveler demand.

In the future, the rise in the middle class in emerging economies of Brazil, Russia, India, China and South Africa (the BRICS nations) will be increasingly important to the recreational travel market and, consequently, trip choice and patterns. For example, the UNWTO reports that, for the last decade, China has been the fastest-growing tourism source market in the world.

Some of the other themes that will also be important in travel include medical tourism (for example, people traveling out of country to have plastic surgery and other medical procedures abroad, as specialist operators offer options to combine surgery and holidays), the aging population (many of whom will have prior experience of leisure travel and disposable incomes that will shape their choices of trip/destination), and “slow travel” (that is, people choosing to savor the experience of travel by lingering more and racing less from place to place).

Recreational Vehicles

A recreational vehicle (RV) combines transportation and temporary living quarters for travel, recreation, and camping into one package. RVs also reflect historical, social, and cultural trends, as well as planning and policy issues in transportation. The U.S. Department of Transportation (USDOT) enforces regulations for RVs above 10,000 pounds under Federal Motor Carrier Safety Regulations, while the states license RVs and their drivers.

In 2011, the Recreation Vehicle Industry Association (RVIA) commissioned the University of Michigan to conduct a study of RV ownership. The study numbers revealed that RV ownership in the United States has climbed to record levels with approximately 8.9 million households owning an RV in 2011. The University of Michigan study revealed that the RV buying power and habits of the enormous baby boomer generation is a key factor behind the RV ownership upswing as well as climbing ownership figures among younger and older buyers. RV ownership numbers extend across a 40-year span from age 35 to 75. The study found that the typical RV owner is 48 years old, married, with an annual household income higher than the median for all other households. RV owners are likely to own their homes and spend disposable income on traveling an average of three weeks a year.

From Autos to RVs

Outdoor enthusiasts quickly recognized the camping potential of recreational vehicles. The first RV, Pierce-Arrow’s Touring Landau, debuted at Madison Square Garden in 1910 and featured a back seat that folded into a bed, a chamber pot, and a sink that folded down from the back of the chauffeur’s seat. Los Angeles Trailer Works and Auto-Kamp Trailers also rolled models off the assembly line in 1910, and soon dozens of companies produced what were then called auto campers.

As automobiles became more reliable, people traveled more often, and travelers using more campers demanded more campsites. From 1913 to 1924, Thomas Edison, Henry Ford, Harvey Firestone, and naturalist John Burroughs traveled in car caravans on annual camping trips. Although they slept in tents, they brought along a custom Lincoln truck outfitted as a camp kitchen. The radio and press covered their adventures and they inspired ordinary people to go camping. Campers, called “tin can tourists” because they heated tin cans of food on gasoline stoves alongside the road, founded the first camping club in the United States. In 1919, they held their first rally in Florida, and by the mid-1900s their club had grown to 150,000 members. The club had an initiation, a secret handshake, and an official song, “The More We Get Together.”

During the Depression some people spent between \$500 to \$1,000 on travel trailers to use as an inexpensive home. World War II rationing

stopped consumers from buying RVs, but some companies manufactured units to serve as mobile hospitals, prisoner transports, and morgues.

After World War II, veterans and their young families searching for inexpensive vacations combined with an extensive new interstate highway system to stimulate a second RV boom lasting through the 1960s. In the late 1950s, motorized RVs gained in popularity, but they were still an expensive luxury and less popular than trailers. Winnebago transformed the market in 1967 when the company began mass-producing what it called “America’s first family of motor homes,” five models ranging from 16 to 27 feet long and selling for about \$5,000.

In 1967, CBS News correspondent Charles Kuralt also recaptured the romance of life on the road when he began reporting his *On the Road* series. Over the next 25 years, he wore out several motor homes and covered more than a million miles.

According to Al Hesselbart, historian of the RV/MH (motor home) Hall of Fame in Elkhart, Indiana, the market changed again as RVs became more sophisticated. Modern RV amenities are limited only by budgets and they feature convection ovens, microwaves, washers and dryers, king-size beds, heated baths and showers, and satellite dishes. Sophisticated and state-of-the-art RVs attracted a new breed of adventurer, less interested in camping and more in destinations like Disney World, the national parks, and themed events.

There are more than 16,000 public and privately owned campgrounds across the United States. Public campground facilities tend to be simple but may be located amid great scenic beauty. Public lands are popular for hiking, fishing, whitewater rafting, and a variety of other outdoor recreational activities.

Privately owned RV parks and campgrounds are located near popular destinations, along tourist routes, and in metropolitan areas. They offer a variety of family activities, including swimming pools, game rooms, playgrounds, and snack bars. RV travelers seeking a resort atmosphere can choose from the growing number of luxury RV resorts that offer facilities like tennis courts, golf courses, and health spas.

Planning

Approximately 7.2 million RVs ply American roads, according to a University of Michigan study that the RIA commissioned in 2011. The RVIA

estimates there are at least 30 million RV enthusiasts nationwide, including RV renters. Many people rent an RV to try it out for traveling before they buy one. The U.S. Census of Retail Trade and the RV Rental Association (RVRA) estimated that the RV rental business is a \$350-million industry, with more than 460 RV rental establishments located across the country.

RVs are divided into two main categories: motor homes that are motorized, and towables that are pulled behind a car, van, or pickup. Type A motor homes are usually the largest and Type B motor homes or van campers are the smallest, with Type C motor homes falling in between. Types of towable RVs include folding camping trailers, expandable trailers, truck campers, conventional travel trailers, and fifth wheel travel trailers.

RVs are also divided into classes. Deemed the nicest motor home of the three main classes, the Class A is a motorized RV built on a special chassis designed specifically for motor homes. They are rectangular in shape and usually 30 to 40 feet long. Their large size accommodates the comforts of a house, including a full kitchen and bathroom and self-contained water and sanitation systems. They often feature washers and dryers and foldouts for extra space.

A motorized RV built on a van chassis, a Class B is usually called a “van conversion,” which at 17 to 19 feet long is much smaller than class A models. Living space and amenities are limited in conversion vans and they have portable chemical toilets instead of on-board sanitation systems. Some van conversions have pop-up roofs for additional standing room. The smaller size of a class B makes them easy to drive and some people use them as their regular vehicle as well as for camping.

Built on a truck chassis, a Class C motorized RV is a mid-grade RV, which at 20 to 21 feet long is bigger than a class B and smaller than a class A. They have more amenities than a Class B and fewer amenities than a class A, including self-contained water and sewage systems. Class C RVs have an overhang over the main cab that serves as an extra sleeping area, which compensates for their lack of a separate bedroom. Some class C RVs are designed with slide-outs for extra room when parked.

Bus conversions are buses ranging from home-made RVs converted from an old school bus to professional conversions made from diesel commercial bus liners that have been remade into recreational

Iconic American-made Airstream trailers park in a recreational vehicle (RV) park in the Netherlands in 2012. In 2011, a study found that RV ownership in the United States has reached a record 8.9 million households. There are also more than 12,000 RV-related businesses in the United States producing annual revenues of more than \$37.5 billion.

vehicles. Homemade bus conversions are bare-bones models with barely any amenities, while others feature the amenities of a Class A recreational vehicle.

Towable RVs come in different versions, including fifth wheel trailers, travel trailers, and pop-up trailers. They do not have a motor but instead are usually pulled behind a truck or car if they are small enough. They range from small to large, and from bare bones to full amenities.

RV Companies

Major RV products are motor homes, travel trailers, and folding or camping trailers. Motor homes and travel trailers each contribute one-third of industry revenue, while folding trailers account for about 10 percent of industry revenue. Some manufacturers make “park” models, basically small manufactured homes that require hookups and are designed to be only occasionally moved.

According to the Recreational Vehicle Manufacturing Report, the recreational manufacturing industry in the United States consists of about 900 companies, including Fleetwood RV, Thor Industries, Winnebago, Airstream, and Forest River, and

the top 50 travel trailer manufacturers generate more than 75 percent of industry revenue. There are more than 12,000 RV-related businesses in the United States producing annual revenues of more than \$37.5 billion.

Airstream, Elkhart, and the USDOT

Airstream, maker of luxury recreational vehicles based in Jackson Center, Ohio, is currently a division of Thor Industries and is the oldest manufacturer of recreational vehicles in the industry. Airstream presently manufactures nearly 2,000 trailers and motor homes a year. Airstream makes several models, including Sport, Flying Cloud, Eddie Bauer, and Classic Limited, as well as models for the European market.

In the early 1950s, Airstream company founder Wally Byam took groups of Airstream owners on trips to many parts of the world, creating an Airstream mystique that survives to this day. The Wally Byam Caravan Club formed in 1955 in Kentville, Nova Scotia, Canada, and later the club became the Wally Byam Caravan Club International. Club members still gather every summer, and hundreds

of local clubs hold rallies. Airstreams are still popular and there are over a dozen Airstream Parks across the United States.

More than 60 percent of recreational vehicles are made in Elkhart County, Indiana. Known as the “RV Capital of the United States,” Elkhart offers RV service, repairs, parts, and accessories to dealers, RV campgrounds, and rallies. Another 15 percent of RVs are built in Oregon and California.

The USDOT regulates RVs over 10,000 pounds under the Federal Motor Carrier Safety Regulations, which specify requirements about tires, rims, and load limits. The Department of Transportation allows states to decide licensing and lighting requirements, and regulations vary from state to state, although all of them require current vehicle licensing. A handful of states require commercial driver’s licenses (CDLs) to operate an RV, and more than a dozen require special permits to drive RVs that are over a specified weight or length.

Regional Transit Agencies

The International Energy Agency has predicted that by 2035, there will be 1.7 billion vehicles traversing the world’s roads. Despite the ubiquity of cars, trucks, and recreational vehicles, many people in the

United States remain dependent on public transportation for getting to work and school and for doctor’s visits and essential shopping trips. Most of the passengers on buses run by various regional transit agencies are comprised of students, senior citizens, the disabled, and those who do not have their own vehicles. Passengers are disproportionately African American and Hispanic.

Each state and local authority has responsibility for managing its own public transportation services. State departments of transportation oversee all transportation services, and funding at that level must be authorized by state legislatures. Individual cities and towns provide approximately one-fourth of the budget for regional transit agencies. At the federal level, the Federal Transit Administration works with state and local governments on issues of regional transit. It has proven to be more economical from both the federal and local perspectives to fund regional projects rather than those that are entirely local, which are narrower in scope by definition.

According to the American Public Transportation Association (APTA), which has kept detailed reports of the public transportation sector since the beginning of the 20th century, using public transportation in the United States reduces annual levels of gasoline by the equivalent of 4.2 billion gallons. In addition to drastically reducing the amount of fossil fuels released into the environment, the very existence of public transportation saves Americans 796 million hours that would have been spent stuck in traffic jams. APTA reports that reducing traffic congestion through public transit saves \$16.8 billion each year.

Largest Regional Transit Agencies

The largest group of transit agencies operating in the United States is comprised of nonprofit agencies that function solely to meet the needs of specific groups such as the elderly or the disabled. However, the group most often associated with regional transit agencies (RTAs) in the mind of the public is made up of regional transit authorities. In 2012, there were 1,460 rural transit agencies and 786 urban transit agencies. It is the urban regional transit agencies that serve 98 percent of all passengers using public transportation.

The largest regional transit agency in the United States is the MTA (Metropolitan Transit Authority)

New York City Transit, which transported 3.3 billion passengers over 11.6 billion miles in 2012. Because the service links New York City with surrounding areas, it connects to other transit agencies in New Jersey and Connecticut. Together, these agencies served 4.1 billion passengers and logged 21.3 billion passenger miles in 2012.

The other largest RTAs that serve urban areas throughout the United States are Chicago Transit Authority, Los Angeles County Metropolitan Transportation Authority, Washington (D.C.) Metropolitan Area Transit Authority, Massachusetts Bay Transportation Authority, Southeastern Pennsylvania Transportation Authority, New Jersey Transit Corporation, San Francisco Municipal Railway, Metropolitan Atlanta Rapid Transit Authority, MTA Bus Company (New York City), King County DOT (Seattle), San Francisco Bay Area Rapid Transit District, Tri-County Metropolitan Transportation District of Oregon, Maryland Transit Administration, and MTA Long Island Rail Road (New York City).

Special Needs

In 1968, Congress passed the Architectural Barriers Act of 1968 and followed it up in 1973 with the Rehabilitation Act. Both bills guaranteed that public facilities be made accessible to disabled Americans. In 1977, the Department of Health, Education, and Welfare issued guidelines supplementing those actions by requiring that all state and local bodies receiving federal transportation grants make all programs and jobs accessible to the disabled population.

In 1990, President George H. W. Bush signed the Americans with Disabilities Act (ADA) into law. Among other things, ADA mandated access to public transportation for people with physical disabilities. The responsibilities of RTAs were spelled out by the U.S. Department of Transportation (USDOT) in accordance with ADA, stipulating that transportation agencies must offer complementary paratransit services to disabled Americans not able to take advantage of the fixed-route system provided by the RTA. Subsequently, systems began offering lifts and other aids to meet the needs of disabled passengers. In 1990, when ADA was signed, there were 68 million passenger trips on demand services being offered to Americans with special needs. By 2010, the number of those services had climbed to 190 million.

In addition to offering assistance for the elderly, RTAs are also equipping buses with bike racks to meet the needs of those who travel to and from transit stations by bicycle. In 2001, only 32 percent of buses were equipped with bike racks. That number rose to 74 percent in 2011.

Budget Problems

According to a 2009 report issued by Transportation for America, in 2008 Americans took approximately 10.7 billion trips on some form of public transportation. That amounted to an increase of 38 percent since 1995. Despite this demonstrated need for public transportation, only 18 cents out of every federal dollar spent on the transportation sector is earmarked for public transportation. Thus, the burden falls on RTAs to provide the funds needed to remain in operation.

When the United States experienced a major economic downturn in the early 21st century, RTAs were forced to take action. That action frequently included drastic cutbacks in service, laying off of workers and raising fares at a time when many riders were barely getting by. Since federal funds generally go toward essential construction and equipment, little is done to modernize systems.

The Massachusetts Bay Transit Authority stands as only one example of an RTA that has been affected by 21st-century budget problems. With 15 regional transit authorities operating under the Massachusetts Bay Transit Authority, the state of Massachusetts has one of the most highly developed RTAs in the United States, but even that system fails to reach certain areas within the state. Even passengers who have access to the service do not always have their needs met. Passengers who ride the Berkshire Regional Transit Authority, for instance, experience long waits and frequent transfers, and routes are often indirect. It may take three times as long to arrive at a destination as it would take to travel the same distance by car.

In 2013, the state legislature banned the practice of operating the system with loans. Governor Deval Patrick proposed a \$100 million annual allotment to keep buses within the system running. Another \$12 million was earmarked for improvements. Those funds were not considered sufficient to keep the system financially healthy. Recent budget cuts had already led to the elimination of

routes and cuts in service, including no service after 7 p.m. and elimination of all Sunday service.

In 2008, funding for RTAs increased in response to passage of the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU). Additional funds were allotted as part of President Barack Obama's American Recovery and Reinvestment Act in 2009. The Federal Transit Administration (FTA) continues to dispense federal assistance, grants, and loans. In 2012, for instance, out of a total of \$12.8 billion, FTA dispensed \$103 million in funds to metropolitan and state planning agencies, \$982 million in funds to buses and bus facilities, and \$5.7 billion in funds to urban areas. In addition to those funds, FTA dispensed 1,116 grants to urbanized areas, 470 to buses and bus facilities, and 45 to metropolitan and state planning for transit projects.

Regional Transportation Planning

Regional transportation planning is an interstate or intrastate collaboration among various local, state, and federal agencies to identify and analyze transportation needs of a region and to prepare a guide to the long-range development of the region's transportation system. This transportation plan covers all modes of transport including automobile, transit, bicycle, pedestrian, railroad, freight, and intermodal movements. The first regional transportation plan dates back to 1919 and 1920 when the Detroit Rapid Transit System recommended a multimodal system.

Other regions developed their own transportation plans during the 1920s, often as part of a larger urban planning effort. However, it was the Federal-Aid Highway Act of 1962 that required metropolitan regions to adopt long-range transportation plans in order to qualify for federal funds that shaped regional transportation planning across the nation. For the next 50 years, federal legislation and initiatives fostered integrated regional transportation planning through a variety of regulations and strategies.

Regional transportation planning encompasses a geographic area larger than the borders of local governments but one that is defined by common social, economic, political, cultural, and natural resources, and transportation characteristics. The agencies charged with this planning throughout the United States are sometimes voluntary associations and sometimes councils or commissions authorized by state legislatures. Regardless of the nature of the planning agency, the purpose of the transportation plan is to provide a lucid view of the region's transportation goals, policies, and strategies developed with an understanding of the existing system and financial constraints. The plan may also include an assessment of the current modes of transportation, predictions of future transportation needs, and recommendations for specific actions to address problems and meet the region's mobility and accessibility needs.

The Origins of Regional Transportation Planning

Nearly two decades before the Detroit Rapid Transit System offered the first official regional

transportation plan, the Massachusetts legislature created the Boston Metropolitan Improvement Commission, the first regional planning agency with planning powers. Plans for railroads and roads were among the commission's proposals. The Plan of Chicago, financed by the Commercial Club of Chicago, a private organization, in 1909, included regional proposals for transportation in its plan, which envisioned Chicago in a regional context.

For a brief period from 1913 to 1915, Pennsylvania's Suburban Metropolitan Planning Commission was authorized to create a comprehensive plan, including highways and parkways, for Philadelphia and a 25 mile radius around the city. The most famous of these regional plans was the Regional Plan for New York and Environs, financed by the Russell Sage Foundation and prepared by an advisory committee. The eight-volume document, begun in 1921 and completed in 1929, included regional proposals for transportation for a 5,528-square-mile area with 500 incorporated entities in New York, New Jersey, and Connecticut.

Other planning commissions with visions of regional networks were established in sites across the country during the 1920s. But while transportation planning was included in the work of these groups, it was only one part of their larger responsibilities. It would take another four decades and an expansive highway program to make regional transportation planning a national priority.

The Federal Aid Highway Act of 1962 and Beyond

Transportation historians cite the passage of the Federal Aid Highway Act of 1962 as the beginning of formal regional transportation planning in the United States. President John F. Kennedy signed the bill on October 23, 1962, six months after he had addressed Congress in a speech that stressed the role of multimodal transportation in domestic well-being and international competition. Among other provisions, this legislation required the establishment of a Metropolitan Planning Organization (MPO) in all areas of the United States with a population that exceeded 50,000. The focus was on the urban region rather than merely the city proper.

MPOs were to conduct a transportation planning process that was "continuing, comprehensive, and cooperative" in order to receive federal highway and transit funding. "Cooperative" referred not

only to federal, state, and local governments working together to make and implement transportation plans but also to the cooperation of various governmental agencies at all levels. "Continuing" referenced the need for periodic evaluation and updates. "Comprehensive" particularly included the elements of the planning process for which inventories and analyses were required: economic factors; population; land use; transportation facilities, including those for mass transportation; travel patterns; terminal and transfer facilities; traffic control features; zoning ordinances, subdivision regulations, building codes, and the like; financial resources; and social and community-value factors, such as preservation of open space, parks, and recreational facilities; preservation of historical sites and buildings; environmental amenities; and aesthetics.

New regulations in the 1970s required each MPO to produce a long-range Regional Transportation Plan (RTP) based on projecting demographic, housing, employment, and other conditions at least 20 years into the future and a short-range Transportation Improvement Program (TIP) that provided a schedule of active projects. (See specific entries on these topics for further details.) The planning was required to include public involvement, financial feasibility, conformity with air quality standards, consideration of the environment, and intermodal coordination.

With 90 percent federal funding for interstate highway projects at stake, states had considerable incentive to establish MPOs. Some states had a single MPO; others had many. California, for example had 10 at the end of 1962. For further information on these entities and their functions see the entry for Metropolitan Planning Organizations (MPOs).

From the beginning, not all regional planning organizations were MPOs. The state of Washington, for example, distinguishes between MPOs, which are mandated and financed by federal funds, and regional transportation planning organizations, which are authorized and funded by the state and may include both urban and rural groups. In some rural areas, no official group is designated to focus on the area's transportation plans; in others, the state or a rural planning organization does so.

Until the passage of the the Transportation Equity Act for the 21st Century (TEA-21), federal legislation did not require local participation in the transportation planning process outside urban

areas. TEA-21 awarded a greater share of formula funds to rural public transportation.

In 1999, the U.S. Department of Transportation announced the Rural Transportation Initiative with the stated purpose of increasing the capacity of rural America to play a more integral role in the planning and decision making that shape transportation systems. In 2013, 30 states have some form of rural transportation planning organization. They may be called rural transportation planning organizations (RTPOs) rural planning organizations (RPOs), regional planning affiliations, regional transportation planning agencies, or simply general purpose councils of governments or Regional Planning Commissions that have a rural transportation planning program.

For the first time in federal legislation, Moving Ahead for Progress in the 21st Century (MAP-21), passed in 2012, included a definition of the basic structure and responsibilities of RTPOs. The statute requires RTPOs to have a lead planning agency that serves as the fiscal and administrative agent and provides planning staff support. Designated responsibilities of RTPOs include developing rural regional long-range transportation plans; creating short-range transportation improvement programs; conducting public outreach; and coordinating transportation with other relevant planning areas.

To a greater degree than any other federal program, transportation has a historically strong, consistently funded planning process. Since the Federal Aid Highway Act of 1962, the adoption of long-range transportation for multiple modes of transportation has been encouraged. While much regional transportation planning is led by MPOs, other stakeholders are also involved in the process. In recent years, rural areas have been increasingly part of the process. Businesses, community groups, environmental organizations, and private citizens have an opportunity to be involved in transportation planning through a public participatory process.

Regional Transportation Planning Organizations

Although regional transportation planning organizations (RTPOs) go by a variety of names, including metropolitan planning organizations (MPOs) and councils of government (COGs), they all serve as a primary transportation planning agency for metropolitan areas throughout the United States. RTPOs are the channel through which federal transportation funds are allocated, and they may also serve a wide variety of other functions.

For more than four decades, RTPOs have been responsible for continuing, comprehensive, and cooperative transportation planning. This includes, but is not limited to, the tasks of maintaining a long-range transportation plan, known as the Metropolitan Transportation Plan or Regional Transportation Plan, and maintaining short-range Transportation Improvement Programs. Through these short-range and long-range plans, RTPOs are responsible for transportation planning to improve a region's air quality, increase mobility for the region's residents, and improve transportation safety within a region.

Legislative History

The foundations of regional transportation planning organizations were under construction long before legislation required them. For example, in 1925 Cincinnati endorsed the nation's first

comprehensive plan that integrated concepts of transportation, utilities, parks, and land use.

In 1933 the Tennessee Valley Authority, the first multi-jurisdiction, multifunction agency that integrated economic, social, and physical planning, was formed and became the precursor to metropolitan planning organizations.

Concurrently, the Federal Highway Act of 1934 was the first to allow states to use up to 1.5 percent of federal highway funding to support surveys, planning, engineering, and other administrative work. However, at this time states were still the primary planning agencies, and it took nearly three more decades to establish dedicated funding for planning efforts.

Following the multi-jurisdiction lead of the Tennessee Valley Authority, in 1954 the council of governments movement began in Detroit and spread nationwide. In recognition that many issues were of interjurisdictional significance and difficult or impossible for each local government to solve on its own, these councils provided a forum for elected officials from multiple jurisdictions to act on behalf of their local government to address regional issues.

Planning grew in importance at the same time the council of governments movement gained momentum. The Federal-Aid Highway Act of 1962 was the first to require that states use 1.5 percent of any highway project's federal construction funds for planning. The act further fostered the importance of planning by requiring the use of the "3-C" transportation planning process: comprehensive, coordinated, and continuing.

Building upon the council of governments movement that began in the 1950s, the Federal Highway Act of 1973 created metropolitan planning organizations (MPOs) to carry out the role of regional transportation planning. These organizations were designed to serve as a conduit for allocating federal transportation funds. For a further description of the organizational structure and responsibilities of MPOs, please see the entry on Metropolitan Planning Organizations.

The act also expanded concern for environmental and social issues in transportation planning and required that local planners produce short-range transportation plans known as Transportation Improvement Programs (TIPs). The TIP is a short-term document, usually covering five years, that

implements the long-range regional transportation plan (RTP) through the construction of infrastructure and implementation of transportation management systems. Subsequent legislation has required regional transportation organizations to expand public participation in their planning process and to address environmental and energy issues.

In many states, regional planning organizations' responsibilities extend beyond the federally funded transportation infrastructure planning role mandated for MPOs. For example, regional planning organizations in California are responsible for transportation-related greenhouse gas reduction planning as well as for allocating some nonfederal transportation funds. In other states, regional planning organizations play a role in urban growth management and land use planning.

Structure

Today nearly 400 RTPOs exist nationwide. Each urbanized area in the United States having a population of more than 50,000 individuals belongs to one of these transportation planning organizations. As outlined in Title 23 Sec. 134 of the United States Code, transportation planning organizations must encompass the existing urbanized area and contiguous areas expected to urbanize within 20 years, and may encompass the entire Metropolitan Statistical Area, as defined by the U.S. Census Bureau. According to the General Accounting Office, half of RTPOs represent populations of less than 200,000 while some planning organizations represent millions of people.

In limited circumstances, of large geographic area and transportation system complexity, a metropolitan area may have more than one planning organization. Similarly, metropolitan areas may cross state boundaries, requiring multi-state planning organizations. These cases, however, are relatively rare. Of the 400 RTPOs, approximately 40 existing planning organizations cross state lines.

Title 23 U.S.C. Sec. 134 also states that metropolitan planning organizations "shall consist of— (A) local elected officials; (B) officials of public agencies that administer or operate major modes of transportation in the metropolitan area; and (C) appropriate State officials." In practice, regional transportation planning organizations may be comprised of directly elected officials or appointees from participating governing bodies, including

cities, counties, and tribal governments, as well as other government agencies such as transit service providers or public utility providers.

The policy makers are generally supported by technical advisory committees. The advisory committees may include technical experts, staff from local government agencies, and members of the public. In addition to advisory committees, RTPOs are supported by administrative and technical staff, though the size of the staff varies greatly from region to region. According to a report from the General Accounting Office, some RTPOs are supported by only a handful of staff while others have 100 or more.

Regional Transportation Plans

Sometimes referred to as metropolitan transportation plans, Regional Transportation Plans (RTPs) are planning documents that outline the transportation needs of and planned transportation improvements for a multi-jurisdiction region that may comprise cities and towns, counties, and sometimes more than one state. These plans are intended to improve a region's air quality, provide for increased mobility of the region's residents, and improve transportation safety within a region.

Legislative History

Regional transportation planning is required by federal law, which has evolved greatly over the past century. While the Federal Highway Act of 1934 was the first to allow states to use up to 1.5 percent of federal highway funding to support surveys, planning, engineering, and other administrative work, there was no mandate to fund planning efforts until 1962. The Federal-Aid Highway Act of 1962 was the first to require that states use 1.5 percent of any highway project's federal construction funds for planning. The act further fostered the importance of planning by requiring the use of the "3-C" transportation planning process: comprehensive, coordinated, and continuing.

A decade later, the Federal Highway Act of 1973 expanded concern for environmental and social issues in transportation planning, required that local planners produce short-range transportation plans known as Transportation Improvement Programs (TIPs), and created metropolitan planning organizations (MPOs) to carry out the role of regional transportation planning.

In 1991, the Intermodal Surface Transportation Efficiency Act (ISTEA) included a new requirement that planning organizations engage in "proactive and inclusive" public outreach. This new element of transportation planning law was intended to encourage public participation in the regional transportation planning process. ISTEA also required that local planning organizations consider 15 specific factors to ensure that the transportation planning process addressed issues such as land use planning, energy conservation, and environmental management. Importantly, it mandated that the

RTP must conform to the emissions reduction goals in the State Improvement Plan (SIP) required by the 1990 Clean Air Act. The plans need to contribute to reducing the number and severity of violations of the National Ambient Air Quality Standards (NAAQS) and to ultimately achieve those standards or the RTPs cannot be approved.

In 1998, the Transportation Equity Act for the 21st Century (TEA-21) streamlined the metropolitan transportation planning process and further expanded the role of public involvement in the planning process. TEA-21 also placed additional focus on environmental considerations.

The largest surface transportation investment in U.S. history, the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU, was signed into law in 2005. SAFETEA-LU expanded funding for environmental programs started within TEA-21, and the act implemented a new environmental review process for highways, transit, and multimodal projects.

In 2012, SAFETEA-LU was replaced by Moving Ahead for Progress in the 21st Century Act (MAP-21). While funding formulas had been changed, transportation planning requirements remained essentially unchanged from the 2005 legislation. Practitioners should note that many states impose local transportation planning requirements in addition to federal planning requirements.

Process

In any planning process, the first step is to identify the problems to be solved and issues to be resolved. In transportation planning, this is likely to include estimating future demand for transportation facilities and services. Planners, stakeholders, residents, and elected officials then identify goals and objectives for the region's transportation system.

Planners develop a series of transportation alternatives to meet those goals and objectives, either by changing the supply of or modifying the demand for transportation. Analysts then evaluate the proposed alternatives using complex computer models of transportation behavior, including air quality analyses of projected levels of pollutant emissions.

Analysts present the various transportation alternatives to the public and elected officials, who provide feedback and select a preferred alternative. Once a preferred alternative is selected, transportation agencies begin implementing the plan by

constructing new infrastructure, rehabilitating existing infrastructure, implementing transportation system management programs (e.g., signal timing and congestion pricing), and implementing transportation demand management programs (e.g., flexible work scheduling and carpool programs).

Analysts then collect data to monitor the transportation system. Data collection is an important step in the transportation planning process, allowing analysts and planners to evaluate the success of a transportation program and identify issues that require further attention. This transportation system information, in addition to demographic and economic forecast information, is then used to update projections of future transportation needs, and the process begins again.

Requirements

According to Title 23 Sec. 134 of the U.S. Code, a regional or metropolitan transportation plan must include the following elements:

- Identification of transportation facilities (including major roadways, transit, multimodal and intermodal facilities, and intermodal connectors) with an emphasis on facilities that serve national and regional transportation functions
- Environmental mitigation activities developed in consultation with federal, state, and tribal wildlife, land management, and regulatory agencies
- A financial plan that outlines both estimated project cost and anticipated sources of funding
- Operational and management strategies to improve the performance of existing transportation facilities in order to relieve vehicular congestion and maximize the safety and mobility of people and goods
- Capital investment and other strategies to preserve the existing and projected future metropolitan transportation infrastructure, proposed transportation, and transit enhancement activities

These plans must be updated at least every four years for regions designated as a nonattainment area, as defined in section 107(d) of the Clean Air Act (42 U.S.C. 7407 (d)), or any area that is subject

to a maintenance plan under section 175A of that Act (42 U.S.C. 7505a). All other regions may update their plan every five years.

Long-Range and Short-Range Plans

In addition to long-range (20 years or longer horizon) transportation plans, regional transportation planning organizations must develop a Regional/Federal Transportation Improvement Program (RTIP or FTIP). The TIP is a short-term document, usually covering five years, that implements the RTP through the construction of infrastructure and implementation of transportation management systems. These short-range implementation plans are required by Title 23 U.S.C. Sec. 134 and Title 42 U.S.C. Sec. 7506.

Projects in the TIP must be shown to conform to air quality standards and must be consistent with projects outlined in the RTP. All projects in the RTIP come from the first five years of the RTP. Projects are included in a TIP if they involve federal or state transportation funds, are regionally significant, or increase existing infrastructure capacity.

Residential Location Models

Residential land use takes up almost two-thirds of all urban land, while home-based trips account for a significant percentage of all travel activities. Hence, one of the most vital long-term, land use related decisions in the context of public policy and urban planning is that of residential location.

An urban area is developed from the mutual coupling and synthetic interaction between natural and human factors, and dynamic urban landscapes reflect intersections of economic development and human activities. Large-scale projects, including new sites for shopping malls and transportation infrastructure, illustrate how the physical environment continues to be transformed through the nexus of political, economic, and technological access and control.

It is the conventional wisdom that residential patterns and travel patterns are closely woven. Residential houses are regularly located along the sides of streets or roads. As a result, the population distribution is closely related to the street network.

Urban processes have complex subsystem elements that operate in diverse ways in the same geographical space. Initiating residential land uses pushes the growth of new land uses in the space. The solution to wasteful commuting, then, is minimizing the total commute to and from a city. In the optimal city, most journey-to-work trips would be intrazonal (that is, residence and workplace are in the same zone) and generate very little wasteful commuting.

The residential location model is crucial to the transportation-system planning process because household locations determine demand for community facilities and services, and modeling that

behavior holds great potential for improving long-range travel demand forecasting. For illuminating the nature of location choice, it is useful to understand which attributes impact these choices: both short- and long-term residential mobility decisions are determined by a variety of dynamic and complex driving forces, such as household membership, family structures, job status changes, and other socioeconomic factors involving various behavioral processes and considerations. Labor-force participation, job choice, auto ownership, and wealth investment all influence individual activity and travel patterns, while individual residences serve as a spatial anchor, impacting the spatial and temporal attributes of those movements.

Residential mobility decisions generate a new round of land use growth in a given neighborhood, which is usually symmetrically arrayed around one point of origin, but sometimes with directional distortion. The probability of an initiating residential use spawning another use in this field is a function of the distance away from the central cell, and which cells get developed will depend on how strong the competition is between different land uses being spawned by the particular land use in question.

A residential land use has the potential to spawn any number of different uses, but only one of these will occur in each time period. The spawning process is subject to a series of constraints, some within a narrow traditional neighborhood around the residence in question, which relates to density and type of uses in the neighboring cells, and it is also subject to regional constraints, which limit what each cell might be used for.

Urban residential models should balance the focus on socioeconomic activity and physical change at the level of residential land use and development. These residential models require spatial and sectoral interactions to be handled. Thus, the use of more explicitly dynamic models in urban policy making has great potential.

Researchers have suggested that planners consider various “aspatial” (not related to spatial data) variables, including demographic measurements, such as age, sex, and ethnicity; socioeconomic status, such as poverty, female-headed households, homeownership, and income; environment issues, such as housing density and amenities; linguistic barriers and households linguistically isolated; and

A dense housing development in Ontario, Canada, in 2005. The residential location model is crucial to the transportation-system planning process because household locations determine demand for community facilities and services.

transportation mobility issues, such as households without vehicles. In all cases, a fundamental question is, “What objectives are these households pursuing?” Fulfilling the expectations of households is a major component of public policy related to housing markets, job location, and transportation.

Location choice can also be rigorously constrained by residents’ strong preferences. In general, residential location choice and home type choice should be modeled jointly. This strong linkage between location and home type choice is very helpful to simulate household behavior and move residential markets toward meaningful housing policies. This linkage not only guides the association between the household and the rest of the human settlement, but it also determines, to some extent, the household’s budget for activity participation. With the passage of the Intermodal Surface

Transportation Efficiency and the Transportation Equity Act for the 21st Century, the integrated residential location and transportation model has gained renewed importance.

The Evolution of Research Models

There is a large body of research and analysis on housing choice. Modern research on housing choice was pioneered in the 1960s by William Alonso, who made assumptions based on a model of a “mono-centric” city with a rational complexity that also captured the most important essence of real-world issues: employment opportunities are located in a single center. In Alonso’s study, the residential choice of households is built upon the assumption that a utility function should be maximized by relying on the expenditure in goods, size of the land lots, and distance from the city center.

In the 1970s, other researchers further developed the work of Alonso by relaxing the ideal of a monocentric city filled with employment opportunities, but a weakness of all of these early works is that location is ultimately represented as one variable, that is, distance from the central business district (CBD). These models are, therefore, unable to deal with dispersed employment centers and asymmetric development patterns characteristic of the 21st century.

Geographers and transportation planners have also suggested a “gravity model” to predict the generation and extent of trips. In the early 1960s, Ira Lowry utilized the gravity model for residential location modeling, known as the Lowry model, wherein he hypothesized that retail trade and services are located according to the residential demand and that residences are distributed in relation to combined retail and basic employment. Workers are assumed to start their trips to home from work and distribute themselves across possible residential locations in relation to a gravity model. This important feature of the Lowry model dominates residential location models in many empirical applications.

Another school of research on residential location modeling is built on discrete choice theory. In the context of residential location, the consumption decision is a discrete choice between alternative houses or neighborhoods. Daniel McFadden in 1978 represented the earliest attempt to apply discrete choice modeling to housing location. Many

follow-up studies differed significantly in their model structures, the choice dimensions, and the explanatory variables considered in the analysis.

A variety of hypothetical urban simulations demonstrate the diversity of model types that can be handled within the framework as a prelude to more policy-relevant research and applications. In urban residential modeling, there are many intricate and dynamic models based on elaborate decision processes, where simulation must be based on customized software if their space-time properties are to be explored effectively.

However, these models have been criticized for being remote from policy, and lacking a focus on real-world planning applications and reflecting the serious disconnect between socioeconomic models—which form part of the urban economics, regional science, and transportation traditions—and this simulation-based, spatially explicit modeling. In other words, urban simulations have been marked by a lack of application to real policy contexts, notwithstanding their obvious relevance to topical problems such as urban sprawl.

Changes of the quantity and scope of residential land use and location choice decision have a profound impact on urban residential development and function, as well as on the role of the city within the region. Amid the variety of development challenges and opportunities spanning the urban landscape, life cycles apply both to the physical stock and the activities that occupy the space over time.

Residential land uses are structured through their life cycles. Urban simulations can be developed to great effect using powerful methods of visualization built around geographic information systems (GIS). Given the intensified globalization and competition in the context of time and space, understanding and harnessing the residential location complexity requires various mathematical modeling and planning in relation to all facets of cities and regions.

In recent decades, a number of modeling strategies have been developed and adopted to better understand and predict residential land use, such as cellular automata and agent-based modeling. At the same time, various urban modeling methods are being constructed based on an understanding from empirical studies.

commuters used trains, buses, and automobiles in order to make their commutes. However, more recently, some have begun to commute from their home in the city to a day job in the suburbs and then to return at night to the city. This phenomenon has been termed "reverse commuting" as the commuting direction is the reverse of what has been the normal commuting direction, which is from the suburbs to the city.

There are benefits to reverse commuting. One benefit is that the reverse commuter travels in the opposite direction to the main body of traffic. This is usually less stressful because most of the traffic is moving in the opposite direction, which opens the road for the reverse commuter. It also benefits the transportation company in the case of buses or trains because their passenger load is increased.

Generally, the reasons for commuting even long distances have been lower housing costs and better schools in the suburbs offsetting the cost of travel to jobs in central cities. However, for reverse commuters a good job in the suburbs may or may not be matched in the inner city, where housing costs may be higher and the schools often of lesser quality. On the other hand, the cities are centers of culture and entertainment so young people may find reverse commuting to be rewarding. In contrast, the family interests of those commuters with children may direct them toward suburban living and urban employment.

New York City

The New York City area is a strong example of the traditional commuter pattern. Rail transport has been developed to carry commuters from all directions—Long Island, Westchester County, New Jersey, and southern Connecticut—into New York City on lines such as the Long Island Rail Road, Metro North, and New Jersey Transit. This promoted the suburban development of 120-mile-long Long Island. In recent years, reverse commuting has become very important to the continued development of Long Island as a business center in its own right.

Although reverse commuting is somewhat less prevalent in New Jersey and Connecticut, which have their own central business districts—such as Newark, New Jersey, and Stamford, Connecticut—Metro North and New Jersey Transit lines provide both commuter and reverse commuter transportation.

Reverse Commuting

Commuting is taking transportation for some distance to go to work, attend school, or for some other regular activity. After World War II, a great many people moved from the city to the suburbs. From there, many middle- and upper-income workers then commuted into the city from their homes in the suburbs. They then returned at night from their city jobs to their suburban homes. The

Reverse commuting from New York City is growing. As of 2010 it was at 300,000 people per day and growing. The reverse commuters left the city for Long Island, New Jersey, and other locations.

Southern and Western Patterns

Commuting and reverse commuting followed different patterns in the Sun Belt of the south and southwest. Unlike the older northern Frost Belt (or Rust Belt) where the older, more traditional cities were much more centrally developed, newer Sun Belt cities, such as Washington, D.C., have spread out significantly as businesses sought less expensive office space. The D.C. metropolitan area urban sprawl into Maryland and Virginia was caused by several factors. One was the limit on the height of buildings in Washington.

A second factor was the existence and extent of its robust transit system, which allowed people to take the Metrobus or Metrorail or to carpool via high-occupancy vehicle (HOV) lanes rather than engage in individual driving. The result has been a more decentralized or polycentric development pattern. Other urban areas have had similar experiences, and many if not most commutes (even in older cities) are now suburb-to-suburb rather than suburb-to-central city. For example, in Los Angeles the vehicle traffic can be much heavier in the morning on the Santa Monica Freeway leaving downtown Los Angeles than coming into Los Angeles.

Legislators Promote Reverse Commuting

A stimulus for reverse commuting was the 1996 Welfare-to-Work legislation adopted by Congress. An issue that was debated in the legislative process was the role of public transportation in getting people to work. Since the inner areas of older cities have decayed and, in many cases, have been resistant to urban development, a grassroots movement to promote reverse commuting for jobs emerged. The Job Access and Reverse Commute (JARC) Program was enacted to provide funding for transportation services to aid welfare recipients and other low-income individuals in part by aiding reverse commuting. The 2005 Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) provided Federal Transit Administration funds for JARC programs.

Recent research on reverse commuting has found that lacking a means of transportation is a major form of social exclusion in the United States. The presence of an urban unskilled “army” or workers without access to bus or rail transportation is a major impediment to their employment and economic development.

In sociogeographical terms, this is a “spatial mismatch” that can be remedied with access to transportation. It is a policy concern that first emerged following the urban riots of the late 1960s when studies identified a lack of job opportunities as a significant factor leading to the civil unrest.

Studies of reverse commuting have been focused on a number of cities, suburban, and other localities. Studies of reverse commuting have been made of Staten Island (New York City Department of Planning), Chicago, California, Philadelphia, Kansas City, and other locations such as Onondaga County, New York. Research has pointed to the development of communications technologies that allow suburban back-offices to communicate easily with urban-core offices, further encouraging business decentralization.

Risk Analysis/ Assessment

Preventing and recovering from events that halt or delay people and products in transit is important to economic growth and security. Grounded in safety and systems engineering, risk analysis became closely identified with assessing and reducing risks associated with nuclear power reactors after the 1979 accident at Three Mile Island in Pennsylvania. It also has been applied to hazardous waste management, control of biological and chemical agents, food security, medical decision making, and natural hazards.

The context for this introduction to risk analysis was an analysis developed for a 60-mile segment of Amtrak's Northeast Corridor passenger rail line between Trenton, New Jersey, and Penn Station in New York City, a stretch of rail that is shared with the New Jersey Transit commuter line.

Risk Assessment

In the context of transportation, risk assessment answers the following three questions:

1. What disruptions can occur?
2. What are the chances that serious events can occur?
3. What are the health, ecological, and economic consequences if the events occur?

Analysts create scenarios, such as a major bridge failure, a leaking tank car, or a terrorist attack on a train or a rail station. They use event or fault trees to build out risk assessment scenarios. Event trees begin with the event and follow it through each stage, whereas fault tree analyses start with an end state and work backward to identify the event or sequence of events that triggers the most serious consequences.

In the case of short-term signal and power failures, and other short-term problems, the likelihood of an event can be estimated from historical records or expert experience. When there is no historical record, such as a major bridge failure or a terrorist attack, the event is assumed as a given.

Death is at the top of the consequences list, followed by injuries, psychological distress, ecological destruction, and economic impacts. For example,

a research team simulated the consequences of a bridge failure of one-year duration and an industrial accident that sent a lethal plume of chlorine into the environment.

Researchers can measure the immediate and local impacts of a bridge failure by estimating how many people and how much cargo was halted and for how long, and how much physical damage there is to the rail system, as well as any injuries and fatalities. What they cannot as easily estimate is how many people will lose confidence in the rail operations, and consequently drive to work, and how many business owners will shift their operations if too many serious events occur with long-term regional consequences. It is also difficult to readily assess the length of the impact.

For example, the terrorist attacks in the United States on September 11, 2001, that used commercial aircraft, and the London subway bombings in 2005 dampened public use of these modes for many months. Risk assessors, in short, estimate the likelihood of specific events and assess their consequences as the impacts ripple across the landscape and through time.

Risk Management

The focus of risk managers is to determine what to do to eliminate or reduce the consequences of a damaging event. Managers answer three questions:

1. How can consequences be entirely or partly prevented?
2. How can recovery be enhanced if the scenario occurs?
3. How can key local officials, expert staff, and the public organize to reduce the consequences?

Risk managers control human, financial, legal, and educational resources. In the case of the rail system example, managers can improve maintenance; add monitoring equipment at stations, on tracks, and trains; improve energy networks in order to reduce the chances of power losses; add more security officers; and improve the capacity of their workforce to respond.

Yet, the best efforts to prevent risk events sometimes fail. Risk managers need resilience plans to restore the system as soon as possible. If the passenger trains stop running or freight is blocked by

a bridge failure, management needs a method of bypassing the blockage and offering alternative mode choices, and it needs to develop a process to rebuild the system, as well as the public's confidence in it.

The most consistent problem in risk management is misunderstanding about who plays which roles in preparing for, responding to, and recovering from an event. Transit workers and upper-level managers should know how to communicate with passengers, how to prevent panic, and how to deal with suspicious people and objects. For example, one research group developed a 15-minute video for the U.S. Department of Homeland Security intended for rail workers who walk the tracks looking for potential dangers and for suspicious people, a 25-minute video about chemical weapons for subway personnel, and are currently preparing one for bus drivers.

Risk analysis is a multidisciplinary field, and books written by scholars with different backgrounds provide numerous perspectives. Risk analysis as a discipline is moving very rapidly, and so those interested in the topic can also consult *Risk Analysis: An International Journal*, especially "Ten Most Important Accomplishments in Risk Analysis," a 2012 article that summarizes what are believed to be major accomplishments during the last 30 years.

Road Diets

"Road diet" is a common term referring to roadway reconfiguration. The most common example involves converting an undivided four-lane road into three lanes made up of two through lanes and a center two-way left-turn lane. The remaining road space can be reallocated for other uses, such as transit vehicle lanes, bike lanes, pedestrian walkways, or parking. The resulting improvements generate benefits to users of all transportation modes and can include reduced vehicle speeds, improved mobility and access, reduced collisions and injuries, and improved quality of life in the community being served.

Studies have shown that road diets undertaken in various cities have had multiple benefits, including decreasing vehicle travel lanes for pedestrians to cross, reducing the likelihood of accidents; providing room for a pedestrian crossing island, improving safety for bicyclists when bike lanes are added; providing the opportunity for on-street parking; improving vehicle (including bicycle) and pedestrian mobility and access; reducing rear-end and side-swipe crashes; and improving speed-limit compliance, which decreases crash severity when crashes do occur. In transportation planning and engineering, road diets have also been used

successfully in “weaning” traffic off some roadways, also known as reversing induced traffic.

Why Put a Road on a Diet?

During the past several decades, there have been many roadways constructed in urban areas that have four lanes. When a road is widened, it often comes with a trade-off: more and wider lanes, with less sidewalks and paved shoulders. In many cases, these roadway improvements allow more cars into traffic streams, encouraging communities to become more car dependent. These changes often generate higher vehicle speeds, noise, and danger to people trying to walk, bike, shop, or live on or near main streets.

Use of public transportation is sometimes discouraged when pedestrians have difficulty crossing four lanes of traffic to get to a transit stop. Minimal areas of sidewalk and vegetation also detract from a community’s visual appeal and can impact the health of neighborhoods and businesses on many levels.

When drivers use four-lane roadways, they assume that there are always spare lanes in their direction. They tend to drive faster than they should. Motorists using multilane roads seek to match speeds of other drivers, and speeding drivers tend to set prevailing speeds. As traffic volumes increase, especially at rush hour, risk of high-speed driving increases.

During peak volumes of traffic, right- or left-turning movements occur. When a car stops in a moving traffic lane to turn left, it causes congestion, blind spots, unsafe lane changes, and changes in vehicle speeds. Quick lane-changing maneuvers can lead to serious rear-end crashes. Drivers may also move from lanes of slowing traffic directly into the backs of other vehicles that have slowed for their turns. These are only a few examples of traffic and driving behaviors on four-lane roads that have been known to cause accidents.

Benefits

When roadways have been modified from four travel lanes to two travel lanes with a two-way left-turn lane, research has shown a 29 percent reduction in all roadway crashes. Road diets provide a center turn lane so that left turns are simpler. A driver crosses only one lane of traffic at a time, resulting in fewer blind spots. With an undivided four-lane road, a driver must find a gap in two or

Two lanes of a highway overpass undergo demolition in Marseille, France, in 2011. Among those roads that may make good candidates for reconfiguration are those with 8,000 to 15,000 average daily traffic (ADT) and those with safety issues.

three lanes of traffic at once to make a left turn. With only three lanes of traffic, there are also fewer intersection conflicts.

The benefits to pedestrians include reduced crossing distance and fewer midblock crossing locations, which account for more than 70 percent of pedestrian fatalities. There are fewer blind spots because there is only one lane in each direction, thus there is less obstruction by traffic. Also, top vehicle speeds in a three-lane system are generally lower. Finally, some road diets reallocate “leftover” road space for pedestrian crossing islands.

A roadway that is reconfigured to create bike lanes is being met with much success and enthusiasm in many cities. The installation of bike lanes significantly increases safety for cyclists and encourages more people to commute by bicycle.

Without bike lanes, a cyclist is always at risk of being involved in a motor vehicle collision, of being “doored” by someone getting out of a parked car, or being “mirrored” by motor vehicles passing the bicycle so closely that their mirror hits the cyclist. Many people are embracing the rise of bicycle commuting because it can enhance the health and well-being of their communities.

Installation of bike lanes, sidewalks, and vegetated areas adds to the general appeal of a roadway and adjacent neighborhoods. If sufficient space is available, cities can add trees along the sidewalks for aesthetics. Trees along streets change the feel and character of a roadway. After a road diet and the addition of landscaping, the message given by a street is that “this is a nice community; please slow down and enjoy.”

Road diets can lead to improvements in use of space, making walking and bicycling more pleasant. Other benefits include the economic impacts on businesses of a street that caters to all users, as well as increases in real estate values and enticement of additional smart growth.

Potential Road Diet Candidates

When considering a road diet for a particular site, city planners may use some guidelines established through research and case studies of road diets already implemented. Location criteria may include the following: moderate traffic volumes (8,000 to 15,000 average daily traffic, or ADT), roads with a history of safety issues, main streets, commercial reinvestment areas, economic enterprise zones, entertainment districts, historic streets and scenic roads, transit corridors, and popular bicycle or pedestrian routes.

Road diets can be low cost if planned in conjunction with reconstruction or simple overlay projects, because a road diet mostly consists of re-striping. Roadways with moderate traffic may be good candidates for a road diet and should be evaluated for feasibility. It has been shown that roads with 15,000 ADT or less have had very good results in the areas of safety, operations, and livability. Driveway density, transit routes, and the number and design of intersections along the corridor, as well as operational characteristics, are some considerations to be evaluated before deciding to implement a road diet.

An evaluation should be conducted to analyze and understand the effects of the proposed

changes, obtain input from community members, and ensure the appropriate elements are included in the project. Of the various configurations for a road diet, it must be decided which one, with which components, will best suit the needs of the local motorists, pedestrians, and cyclists, as well as those of homeowners, retailers, and other business establishments.

Improvements to intersection turn lanes, signing, pavement markings, traffic control devices, transit stops, pedestrian and bicycle facilities, and landscaping all may need to be planned to support this concept.

Road Ecology

Road networks enmesh North America in a rapidly expanding and intricate web that is designed to meet the demand for fast, efficient transportation. While roads consume and directly alter

landscapes, they also indirectly affect areas and wildlife surrounding road infrastructure; for some wildlife populations, these road effects may be experienced hundreds of miles from the road itself. Importantly, the ecological consequences of roads not only are observed for each individual road but also are cumulative, as each road in the network becomes closer and closer to the next.

It follows, then, that the highway infrastructure in North America has been suggested for decades to be the single greatest threat to many wildlife populations and to biodiversity conservation. Primarily, this is because vehicular traffic on highways causes millions of wildlife deaths every year. However, in tandem, roads also directly interrupt ecological processes (such as stream flow or runoff), may contaminate air and water, and increase light and sound pollution.

Roads also challenge animal survival through habitat fragmentation (the loss and breakup of suitable habitat), road avoidance, the imposition of barriers to movement, and alteration of ecological processes (for example, changes in predation rates). Any one of the latter can increase the risk of species extinction or extirpation. The discipline of road ecology, which was developed to understand and attempt to mitigate these risks, describes the diverse science that merges biology, ecology, geography, and transportation and urban planning.

Road ecology and the specific effects of roads on wildlife have been studied since the 1970s and a number of key literature reviews have summarized research on road-related ecological disturbance effects. The *Proceedings of the International Conferences on Wildlife Ecology and Transportation* (ICOWET), offers alternative sources that describe road ecology. Recent research trends (that is, in the last 15 years) have focused on wildlife mortality, pollution/contamination effects of roads and vehicles, and mitigation approaches. In turn, these investigations have focused on mammals, birds, amphibians, and fish.

Although small mammals have been the focus of most fragmentation experiments, large mammals have received the greatest attention in road mortality and mitigation studies. Other authors have accurately noted that insects also are killed in vast numbers. Yet, despite their potential keystone role in ecosystem services, the effects of such mass insect kills remain poorly documented.

A bus approaches a caribou in the road in Denali National Park in Alaska. In Canada's Rocky Mountains, ungulates do not have their movements impaired until traffic reaches high volumes, around 15,000 vehicles per day, but carnivores may be impacted even at low traffic volumes of 500 to 5,000 vehicles per day.

Ecological Effects

Road effects on wildlife are classified as direct or indirect. Direct effects are those that immediately impact the animal, for example, when the animal is killed by a vehicle. Indirect effects are those that influence the animal negatively in a secondary way, for example, the animal avoids crossing a road due to fear, or animals leave an area due to increased human presence. With specific reference to terrestrial wildlife, the key disturbance effects include habitat loss and degradation of quality (for example, through pollution or alteration of processes), reduced movement and loss of access to vital resources, road avoidance and mortality, increased human exploitation, and disruption of ecological processes that maintain wildlife populations. Some ecological effects are so pronounced they are identified as "phenomenon" that may include both

direct and indirect effects; these include the “barrier effect” and the “road effect zone.”

The first of these, the barrier effect, results when animals cannot move across the landscape due to the effects of traffic on the highway. These effects may apply to terrestrial or aquatic animal species. Here, terrestrial animals are either directly killed by vehicular traffic as they attempt to cross between isolated habitats, or they may avoid crossing roads for fear of detection. Aquatic species are affected by changes in stream turbidity, alteration of stream flow, narrowing of stream channels, pollution, and loss of necessary habitat for dispersal.

In ecology this phenomena is termed “the barrier effect.” The second ecological effect is the road effect zone, which includes areas adjacent to roads into which adverse effects propagate. Depending on the specific effect, the consequences may be experienced hundreds of meters/yards into the surrounding habitat and can vary over time (of day or season), and can vary for each terrestrial or aquatic species affected. The development of a road through a previously contiguous habitat can result in increased “edge effects,” which include but are not limited to increases in light and sound penetration into forest core areas, alteration of species that exist along the edge, crowding of species into habitat patches that are farther from roads, changes in aridity of the forest due to greater wind penetration, tree damage and windfall, and alteration of soil and water quality.

Indirect effects also include changes to animal movement patterns and behavior in areas adjacent to roads. Road avoidance has been documented in mammals and reptiles, but some animals such as coyotes have learned to cross roads when traffic volume is low. Such adaptive behavior is no guarantee of survival, however, as wildlife have not evolved in a context that would allow them to comprehend the speed of vehicles. Other researchers have found that road traffic causes adaptive shifts in home ranges for species such as black bears, grizzly bears, cougars, bobcats, coyotes, and wolves.

The permeability of a road (that is, how easily it can be crossed) is directly related to traffic volume. Different tolerances and crossing abilities have been observed for various species. In particular, in the Rocky Mountains of Canada, carnivores experience a significant reduction in movement rates at moderate to low traffic volumes (500 to 5,000 vehicles per day) compared to ungulates, whose movement

rates were not impaired until high traffic volumes (15,000 vehicles per day). This has conservation implications, as lower permeability results in fewer individuals of a population moving across a road, which in turn can decrease genetic exchange and reduce genetic diversity and adaptability.

Behavioral and morphological conditions may also affect species survival in road-fragmented habitats: small and slow-moving species, herd or social animals, and those species or sexes of species that must cross roads more often may be at increased risk of mortality. As an example, researchers have found that amphibians can be difficult to see and during migratory periods may be struck in great numbers on roads.

Likewise, herding (for example, elk) and social animals (for example, wolves) can be hit in greater numbers on roads because of their affinity and need to stay together. Species that have a primary provider during certain times of year (for example, one animal is dependent upon the other during the denning period) have shown higher rates of mortality by sex and reproductive status.

Other animals, such as grizzly bears, have been observed to alter their movement patterns within home ranges to attempt to minimize such contact. Importantly, roads can also attract wildlife, providing sources of water, food (for example, grasses or small mammals), warmth (for example, sleeping on roads as they hold heat), or easy travel relative to movement through adjacent habitat (for example, when snow is deep, animals may use roads to move).

Roads alter the microclimate health in adjacent areas, which can disrupt natural processes that are critical to wildlife community structure and function. For example, water flow, fire occurrence, nutrient cycling, predation rates, and the increased presence of invasive species may all affect wildlife species abundance and distribution. Moreover, contamination may occur when road maintenance chemicals are applied or when vehicle discharges spread into adjacent air, land, and water. As an example, two-stroke engines (such as are found on snowmobiles) discharge particulate matter and heavy metals many hundreds of meters/yards into forests and fields adjacent to roads. Heavy metals have direct impact on plant and animal species adjacent to roads but may also move through the trophic chain, resulting in bioaccumulation of toxins in other species.

Likewise, salt and slip reduction products, used in winter to maintain travel and mitigate the effects of ice, can seep into surrounding habitats during periods of snow melt, or are pushed into adjacent rights-of-ways during road clearing. Soil erosion from road maintenance may also affect stream flow and vegetation adjacent to roads. Increased sediment loads and contaminants in water systems affect both aquatic and terrestrial species.

Lastly, roads play a role in the transport of invasive wildlife species and disease. The creation of road networks is now recognized to facilitate connectivity and transport of plants and animals from previously isolated patches into new habitats (for example, domestic squirrels, invasive insects). Such events can trigger trophic changes in species composition and dynamics, and the resulting cascade of effects is not understood.

Mitigation

“Highway mitigation science” describes the research and design of roadway and human-made structures that serve to reconnect habitat that has been fragmented by the road: the aim is to reduce mortality and reconnect individuals within a population or reduce mortality of wildlife on highways. The characteristics of roads (for example, width, traffic volume, speed, and type) and condition of the driver have been studied and found to influence vehicle-wildlife collision frequency and lethality. For instance, wildlife species reportedly are hit by vehicles less often if roads have high embankments and more often when heavy forestation is adjacent to roads. Notably, vehicular collisions frequently are related to the intersection of migration routes and roads.

Mitigation includes built structures and is implemented in places where wildlife mortality on roads becomes problematic to endangered species, or where human-related deaths and vehicle insurance costs become too large. Road mitigation includes such things as raised crossing structures, culvert underpasses, open spans of highway over creeks, exclusion fencing, and speed zones, which, in theory, are developed to facilitate movement of wildlife across roads and reduce wildlife mortality.

While this is a growth area of research, most early studies focused on the comparison of effectiveness of mitigation types, indicating that open spans of highway or overpasses of much greater width than 75 yards have efficacy for movement relative to

other mitigation structures. More recent studies have examined the effective placement of mitigation structures and have found that placement of structures tends to follow engineering requirements of building, or are single species in design, rather than addressing ecosystem or multispecies movement requirements.

Road Inventory

A road inventory is a compiled data resource that can provide various categories and layers of information based on the structural conditions and status of roads within a given area or jurisdiction. Road inventory is very useful, not only for planning purposes in the maintenance of safe surface transportation, but also for its utilization during funding requests. Any detailed request for thoroughfare improvement or widening, bridge repair, or highway construction that is submitted to the U.S. Department of Transportation (USDOT), or to similar bodies at the state level, generally requires a road inventory as one of its core documentation features.

Development

Road inventory reports have for decades been considered an essential part of the management, planning, and funding cycles of local, state, and federal transportation authorities and administrators. The hundreds of billions of dollars budgeted for and spent from the federal level on down for roadway design, construction, and maintenance, along with such integral or ancillary features as sightline improvements, bridges, culverts, tunnels, signage and traffic signals, electronic monitoring systems, ecological and civil remediation, and other matters have been a powerful incentive for the development of better road inventory capabilities.

This funding availability and its often strict compliance rules and guidelines have provided longstanding reasons for localities and states to progressively—and competitively—develop their ability to demonstrate road-improvement need, provide evidence of intelligent oversight, and show competence in project management.

Mileage Reports

Most state transportation authorities compile, produce, analyze, and file annual reports, including road mileage data within their jurisdictions. The essential data will often be footnoted or electronically layered with reference to such criteria as segment mileage and name, jurisdiction name, year of initial construction, roadway dimensions, material makeup of pavement, shoulder width and makeup, speed limits, general condition, status of maintenance activity or scheduled work, type and weight of conveyance restrictions, erosion or related risks, and special notes. Increasingly, the road inventory documentation may be linked to further documents that provide information on how certain road segments are part of proposed or budgeted projects within a five-year horizon.

Responsibility within a given jurisdiction may extend well beyond the immediately obvious. In South Dakota, for example, the transportation department (SDDOT) maintains an annually updated road inventory of all the nonstate public roads. The motivation behind this effort is revealing. The SDDOT states

The roadway information is necessary, to meet reporting needs, support in departmental decision making, development of state's certified

mileage report, and other mileage statistics utilized by state and federal authorities for the purpose of funding allocations and special studies.

Considerable effort and state resources are expended in what is in this case a collaborative effort between SDDOT, the Northeast Council of Governments, South Eastern Council of Governments, First District Association of Local Governments, Planning and Development District III, and officials and employees who staff a full range of other federal, state, county, township, and city agencies and panels that each exercise some measure of jurisdiction over public roads in South Dakota. Each of these entities, by virtue of the interconnectedness of the roadway system and its support structures, has some insight into and data-gathering ability for those public roads that the state itself does not control or maintain—but that often prove to be vital links in the planning and maintenance of safety, security, and adequate capacity over the entire road network.

Technological Advances

Geographic information systems (GIS) are increasingly important—if not essential—for maintaining compliance with new ways and means of managing road inventory. Their use has become a central component in meeting the expectations of the funding sources that are tasked with receiving, reviewing, and querying the funding requests from all 50 states and thousands of municipalities and other jurisdictions.

The earliest GIS software was developed in the late 1960s; its utilization within the forestry management sphere caught the attention and captured the imagination of many within such domains as urban planning, housing development, conservation advocacy, coastal protection, and transportation policy. Many features have been added and refined by specialists working in each of these fields.

Data typically originated from on-site handheld surveying supplemented by remote sensing technology, such as radar. Ultimately, GIS has been greatly enhanced by the advent of the Global Positioning System (GPS) and the development of compiling techniques and display software that supports this merger of ground-based and satellite-enabled data.

Some states use a linear referencing system (LRS) to more intuitively convey key road inventory

information that may not be clear from the basic x- and-y-coordinate type of data available through GPS and GIS. The North Carolina DOT, for example, has employed a new software system that matches up the fundamental GIS data with its separately derived linear data—such as distance measuring on the basis of landmark point to landmark point. The LRS can show very recognizable and important data, such as the category of planned or ongoing road inventory modifications: route changes, road additions, renamed roads, and road abandonments. LRS also facilitates the generation of both spatial and tabular reports.

Another tool is the geomorphic road analysis and inventory package (GRAIP), which integrates known scientific impacts of roads on water quality. GRAIP is used in conjunction with GPS- and GIS-sourced data. To the road and topographic data supplied by these sources, GRAIP then applies variable indices for surface erosion, sediment flow and accumulation, slope stability, and related hydrology-generated factors. Use of GRAIP has been refined by, among other specialists, a team based at the Rocky Mountain Research Station operated by the U.S. Forest Service.

The design and development of GRAIP stemmed in part from the work of fisheries biologists; the domain of these scientists' expertise converges with that of surveyors and construction engineers, where the physical features to be inventoried include culverts, stream crossings, and heavy roadway drainage areas. Proponents of using GRAIP contend that it can help reduce the costs of watershed management while supporting more intelligent decision making in watershed-restoration projects, each of which has prominent road-surface and right-of-way issues as part of its inherent structure.

Comprehensive Data

Paved roads are only one component of contemporary road-inventory databases. For example, in January 2013, the U.S. General Services Administration promulgated a request for a new contractor to upgrade the road inventory system for the federal land-management agencies, which include such bodies as the U.S. Fish and Wildlife Service, U.S. Forest Service, National Park Service, Bureau of Land Management, Indian Reservation Roads, and Army Corps of Engineers. Noted in the request was the fact that the necessary inventory system upgrade would encompass a broad array of features to include

A map of the Shoshone National Forest in Wyoming was created using U.S. government geographic information system data and ESRI's ArcGIS, a software tool used for road inventories.

“paved and unpaved roads, trails, parking lots, boardwalks, bridges, docks, airstrips, culverts, and signs.”

The solicitation was in compliance with the Moving Ahead for Progress in the 21st Century (MAP-21) program, under auspices of the Federal Lands Transportation Program. This specifically calls for collecting

condition and feature information on transportation assets and to make available the spatial and tabular data in such a way that it can be used in a geographic information system (GIS) to create and disseminate electronic reports.

Nongovernmental Actors

Some citizen-based organizations and privately held corporations use road inventory data in conjunction with other databases to help them utilize information in a holistic manner in accordance with their mission goals. For instance, the Pacific Stewardship, a regional forestry and natural resources consulting firm based in the Deschutes River Valley of Oregon, embraces a wide range of sophisticated mapping technologies. Among these are a forest projection system, landscape management system, and fire modeling and analysis software.

As part of its efforts, Pacific Stewardship has conducted a variety of combined forest and road inventory and vegetation and road inventory surveys.

These have been done on behalf of private landowners, local park management entities, regional stakeholders, natural resources conservation advocacy organizations, and both state and federal agencies. Typical services include vegetation delineation and typing, road and stream mapping and assessment, and customized inventory design, installation, and actual compilation of the data. Training, from the outset to the finalization of data compilation, is an essential part of the inventory service.

Pacific Stewardship notes that by installing a comprehensive road inventory, conservation and forestry clients can tap the data to intelligently “build maintenance and repair schedules, expand road networks for future harvests, and identify roads for decommissioning.”

Software tools in use by Pacific Stewardship come from several different technology and service provider companies. The company ESRI, for example, is tapped for its ArcGIS and ArcPad systems, which Pacific Stewardship uses for field-based mobile mapping, plot installation, and navigation. Also in use is ArcPad Studio to create customized data collection forms. Handheld mobile computers are used in the field; these are generally of the ruggedized Nomad line manufactured by Trimble, and are loaded with consumer- and survey-grade GPS data—using software. These platforms also operate Terrasync and Pathfinder Office software for purposes of custom data dictionary compilation and post-processing work.

Bikeway Inventory

In Massachusetts, state transportation authorities (MassDOT) have inherited and built upon very ambitious bikeway plans first promulgated by local towns, counties, and other substate bodies. In recent years, the state has found it necessary to compile and produce an increasingly accurate and comprehensive set of bikeway inventories, policy statements, and expansion and funding plans for this growing segment of its official responsibility.

In its 2011 year-end report, MassDOT expressly detailed the needs and priorities of this effort as it sought to catalog and categorize bikeways across Massachusetts in its Bicycle Facility Inventory (BFI), and to define the plans for each segment of what has become termed the Bay State Greenway. The MassDOT’s “Bicycle Facility Inventory Report 2011” states the following:

While a fundamental purpose of the BFI is to reflect existing accommodations for bicyclists, the BFI more broadly attempts to represent the whole spectrum of bicycle facility development . . . The spatial data in the BFI contains existing facilities across the Commonwealth, as well as projects in construction, design, or feasibility study phases, and those that are simply proposed or envisioned at this time. Both on-road accommodations (bike lanes and shared-use lanes on marked and unmarked routes) and off-road (shared-use paths) facilities are included. The BFI is intended to be useful not only as an inventory, but also as a planning tool, to show not only what bicycle facility network exists in 2011, but what may be developed in the future.

Getting to the heart of the matter, MassDOT specified that the BFI would be utilized in much the same manner as its annual road inventory (RI), that is, to clarify policy, prioritize planned activities, and empower the funding request function. MassDOT explained the relation—and integration—of the two document systems in the following terms:

Like the RI, the BFI requires continuous maintenance. It is intended to form the basis for development of other data by a broad range of users, who require continuity across update and release cycles and who need dependable keys to attach their own data. A portion of the BFI consists of data maintained in the RI itself, and as public data, is subject to review and requests for corrections by other public agencies, as well as the public at large. Because on-road accommodations are tied dynamically to the RI, improvements in that data layer are automatically inherited by the BFI.

To build and expand the usefulness of the bikeway inventory, MassDOT tapped a wide range of inputs, applying data sourced from regional planning entities, municipalities, advocacy groups, and project engineers. In order to maintain consistent identification of key bikeway features, the BFI uses a unique identifier for every feature that is carried forward in subsequent research and funding cycles.

The data in the BFI is layered and linked in order to include the latest updates on the greenway plan, local project status, physical characteristics,

involved agencies and entities, usage statistics, and external references. Design review was in process for more than 70 road-segment improvement projects at year-end 2011, MassDOT noted, to include new bicycle lanes, usable shoulders, shared-use markings, and multiuse trails.

Road Pricing Schemes, U.S. and International

Road pricing involves charging road users directly for their use of road space in accordance with their level of usage. Systems may be divided into urban and interurban initiatives. Urban road pricing refers to schemes within defined parts of specific urban areas and/or during a particular time period, and there are a limited number of examples across the world.

Interurban pricing involves charging road users for their use of interurban roads, typically highways of a strategic or trunk nature. Interurban road pricing includes the traditional tolling of privately owned and operated roads, where tolls are principally associated with highway financing, as well as user charges for the publicly owned parts of the interurban road network imposed by government.

There are three principal motivations for road pricing:

- To raise revenue (for example, for the construction and maintenance of roads themselves)
- To ration demand (for example, as a means of combatting traffic congestion)
- To internalize externalities (for example, to enable road users to incorporate the social costs of their road use in their trip-making decisions)

In the early days of the development of the modern transport system, user charges were the principal source of revenue for the financing of both infrastructure and operations, for instance, the turnpikes in the United Kingdom (UK) and the United States. During the 20th century, governments commonly took on increasing responsibility for roads, viewing them as a "public good," and intervened directly in their pricing by moving to financing based on general taxation. Today, there is a diverse patchwork of approaches to the pricing of road use, and varying calls for reform.

Direct-user charges in the form of road pricing are the exception. Tolls, in one form or another, continue to be used on some major highways in some countries, while road-related taxes, such as taxes on car ownership and on fuel, are commonplace

and a major source of tax revenue. Further, there are a number of specific urban road-user charging initiatives that have been introduced as a means of rationing demand and raising revenue.

How It Works

Road pricing starts with the premise that road users will pay a charge or fee when they determine that the benefits of paying outweigh the cost and they will drive accordingly. In situations where the road users do not think the benefits outweigh the cost, they will decide to change their travel behavior to avoid the payment.

This behavior change may involve rerouting, rescheduling, grouping journeys together (for example, car sharing or trip chaining), switching from a car to another mode, or simply reducing travel. Sometimes change will occur immediately, but sometimes it may only occur over a longer period; and longer-term changes may involve more dramatic responses, such as moving a home or work location.

Urban road pricing may take a number of different forms, including "point pricing" and "area charging." Point pricing involves the levying of a price to pass a point on a road, not unlike conventional toll systems. However, a price on a single road is likely to encourage traffic to divert to avoid it, and so most point pricing systems involve cordon charging (or toll rings) in which a series of charging points are established at all entries to a given area. This concept can be extended to a series of concentric cordons, or cells, or a cordon combined with radial screen lines.

Area charging (or area licensing) is another variant of cordon charging, in which a charge is levied to use a vehicle within a defined area, rather than just to enter it. This will also control vehicle journeys wholly within the cordon, which are unaffected by cordon charging (and might, as a result, increase).

Urban Uses

The first urban road pricing scheme in the world was introduced in Singapore in 1975. Initially, this was an area licensing (area charging) scheme to reduce congestion in the city center. Drivers were required to purchase licenses (by the day or the month) to allow them to enter the defined area between 7:30 A.M. and 10:15 A.M. The initial charge was 3 Singapore dollars (\$2.36); this was raised to 4 Singapore dollars (\$3.14) in 1976.

Vehicles with four or more occupants were exempt from the fee. Enforcement was by manual inspection. Subsequent modifications involved extensions into the evening peak hours, the working day, and Saturdays; to a set of charging points on expressways, and to all cars, regardless of how many occupants they had. Different charges were levied for different types of vehicle.

In 1998, the area licensing scheme was replaced by an electronic road pricing scheme in which 97 percent of the 700,000 vehicles in Singapore were fitted with onboard units in which smart cards were inserted. Structures at the entry points and expressway charging points used in the prior system were equipped to identify, interrogate, charge, and, if necessary for enforcement, photograph, all vehicles passing.

Charges are now levied per crossing rather than per day, and vary by time of day and vehicle type. Charges are revised quarterly to maintain speeds at between 12 miles per hour (mph) or 20 kilometers per hour (kp/h) and 19 mph (30 km/h) in the city center, and 28 mph (45 km/h) and 37 mph (60 km/h) on expressways. As a result, charges are lower than they had been with the area licensing scheme for much of the day, and they have been waived on Saturdays.

In 1986, Bergen, Norway's second-largest city, was the first city in Europe to introduce a toll ring (or cordon) charging system. It was introduced with the objective of raising the finances required to accelerate the implementation of a wide-ranging program of transport investment. The system charges all vehicles (other than buses in regular service) a flat fee for entering the city's central business district and operates between 6:00 A.M. and 10 P.M., Monday through Friday.

Toll rings were subsequently also introduced in Norway's cities of Oslo and Trondheim. As in Bergen, the main objective is to raise revenue, and so charges are set according to revenue goals. Both Oslo and Trondheim use electronic toll collection, and in Trondheim, tolls are differentiated by time of day.

In 2003, London introduced an area licensing scheme known as the London Congestion Charge. This covers an eight-square-mile area of central London. (The size of the charging zone was approximately doubled in 2007 with the inclusion of an area west of the original zone, but that western

extension has since been removed from operation.) Drivers wishing to enter the zone between 7:00 A.M. and 6:00 P.M., Monday through Friday, are required to pay the Congestion Charge.

The charge was 5 pounds sterling per day (\$7.77) when first implemented, but it has since risen to 10 pounds (\$15.55). However, there are a number of exemptions, which apply to motorbikes, mopeds, taxis, buses, emergency vehicles, vehicles using alternative fuels, and vehicles whose drivers are disabled; residents of the zone receive a 90 percent discount. It is possible to pay the charge in advance on a daily, weekly, monthly or annual basis, either by phone, mail, Internet, or at retail outlets.

Entry into the charging zone is indicated by a mix of street signs and pavement markings, and enforcement is by Automatic Number Plate Recognition (ANPR), facilitated by a network of fixed and mobile cameras. A fine in excess of 100 pounds (\$155.50) is levied in cases of nonpayment, although it is halved if the fine is paid within 14 days. Implementation costs in the first two years were 190 million pounds (\$295.5 million), more than twice the amount expected, and annual operating expenses are approximately £130 million (\$202.1 million). The system has covered its capital and operating expenses every year since its inception. For example, revenues amounted to some 268 million pounds (\$416.7 million) in the year ending June 2008. All proceeds are earmarked for spending on improved transport within Greater London.

The most recent large city to introduce congestion charging was Stockholm, Sweden. A system of cordon-based variable pricing was deployed first on a trial basis, from January 2006 to July 2006, before it was made permanent in August 2007, following a close public referendum in September 2006. The system charges vehicles registered in Sweden when they pass one of 18 "control points" entering or exiting the cordon (based on the central business district) between 6:30 A.M. and 6:30 P.M., Monday through Friday.

The rates vary from 10 Swedish krona (\$1.50) to 15 Swedish krona (\$2.25), depending on the time of day, for crossing a control point. The maximum charge per vehicle per day is 60 Swedish krona (\$9.00). Exemptions from the charge are awarded to motorcycles, buses, taxis, certain alternative-fuel vehicles (ECO-cars, LPG, and electric), emergency vehicles, vehicles with disabled drivers, and foreign-registered vehicles. There are no resident discounts,

except for residents of one land-locked island from which mainland Sweden is accessible only via the cordoned area. Enforcement is via ANPR, using digital imaging cameras mounted on overhead gantries. The costs of implementation included an investment of 1.3 billion Swedish krona (\$180 million) for the tolling system, plus a massive investment of 2 billion Swedish krona (\$280 million) in related public-transport improvements.

National-Level Experience in Europe

At the level of the European Union, policy regarding infrastructure pricing for road transport largely concerns road freight traffic; the issue of pricing for the use of roads by private car is an issue left to individual member countries. Policy was initially, in the mid-1990s, aimed at limiting competitive problems within the road freight sector caused by the existence of very different methods and levels of pricing for infrastructure use in different member states. For example, vehicles licensed in a country with low annual license duty, plus supplementary tolls, may have had an unfair competitive advantage when competing with a vehicle licensed in a country with high license duty and no supplementary tolls. Thus, charges were permitted to be levied in a nondiscriminatory way on heavy goods vehicles (HGVs) wherever they were registered.

Directive 2006/38/EC revises the Eurovignette regime and represents the current legal position on European road goods vehicle pricing. The 2006 Directive allows the toll to be applied to all HGVs (vehicles weighing over 3.5 tons). It is applied to the trans-European network (TEN), but permits application of pricing to other roads as well. It is also recommended that "revenues from tolls or user charges should be used for the maintenance of the infrastructure concerned and for the transport sector as a whole, in the interest of the balanced and sustainable development of transport networks."

In terms of differentiation, the 2006 directive provides for variations according to a number of factors, such as distance traveled, infrastructure type and location, vehicle type, and time of day. Thus, prices can be differentiated to reflect the key variables determining marginal social cost. However, the legislation still ties the average charge to the average cost of building and maintaining the infrastructure, excluding externalities (except in the case of sensitive areas such as the Alps, where a

markup can be applied and used to finance alternative transport infrastructure).

In parallel with these developments in EU-wide transport infrastructure pricing policy, a number of EU member states have been examining proposals for national schemes for the pricing of heavy goods vehicles. Austria in 2004, Germany in 2005, and the Czech Republic in 2007 introduced their own distance-based road pricing systems for heavy goods vehicles using their national motorway networks. Somewhat removed from the thrust of European policy with regard to the internalization of external cost, they are based on infrastructure capital, maintenance, and operational costs, and might be seen as an alternative means of road financing, though they do incorporate some price differentiation according to environmental factors.

The one European country to have introduced charges for HGVs on all roads, which explicitly includes environmental costs, is Switzerland (not a member of the European Union). Part of these charges is earmarked for investment in new rail infrastructure.

Road-Use Pricing in the United States

In the United States, a number of road pricing initiatives aimed at tackling congestion and raising revenue have been implemented over the past two decades. Legislation in California to attract private capital to investments in new or previously programmed highway improvement projects led, in 1995, to the State Route 91 (SR 91) Express Lanes operating company implementing a variable-toll schedule, labeled as "Value Pricing."

At approximately the same time, the federal government initiated funding for a number of demonstration projects focused on using pricing to tackle road congestion, which, in 1998, it renamed the Value Pricing Pilot Program. Under these initiatives, the United States has led the way in the variable pricing of lanes; for example, variable prices are charged on separated lanes within a highway, such as express-toll lanes or high-occupancy toll (HOT) lanes.

On SR91, the variable tolls on the express lanes range from \$1.25 during off-peak times to as much as \$9.80 on Friday afternoons. Adjustments are made to the tolls every three months based on traffic observed over the previous three-month period. It is reported that speeds on the express lanes are 60 to 65 mph, compared with speeds on the adjacent

free lanes of only 15 to 20 mph, and that, in the peak periods, the express lanes can carry almost two times the number of vehicles as the free lanes.

The San Diego HOT lanes, which operate on an 8-mile stretch of I-15 north of San Diego, are typical of HOT lanes elsewhere. They allow high-occupancy vehicles (public transport vehicles and cars containing two or more people) to travel free, while single-occupant vehicles may access the lanes if they pay a variable toll (\$0.50 to \$8.00).

When it opened in 1998, the San Diego scheme became the world's first fully dynamic variable-pricing operation. The toll varies based on the congestion level, which is analyzed every six minutes, with tolls being modified as necessary. The scheme is seen as having been a clear success, and is being extended to a length of 20 miles.

HOT lanes have also been introduced in Houston, Texas, and Minneapolis, Minnesota, and express lanes in Denver, Colorado, although with less clear-cut success than appears to have been the case in San Diego. Also, variation in the pricing of existing toll facilities has been introduced under the auspices of Value Pricing, such as for bridges in the New York/New Jersey area and in Fort Myers, Florida.

Road Rage

The term *road rage* became popular in the United States in the 1990s as stories increased about drivers becoming violent against one another on the road and while stopped at intersections or parking lots. The phrase often is used interchangeably with the term *aggressive driving*, but there is no clear consensus regarding a specific, encompassing definition. Some contend that aggressive driving includes actions such as intentionally cutting off someone, driving too closely behind, or making rude gestures to another driver; road rage pumps the aggression up a notch and refers only to incidents where actual violence has occurred.

The lack of a broadly accepted definition means that road rage, in most cases, is not considered a criminal activity. Many aggressive driving maneuvers fall under the classification of traffic violations, but in very few cases is it categorized as a criminal offense. Regardless of terminology or legal status, it is clear that dangerous behavior is at the root of both road rage and aggressive driving.

There are many contributing factors and behaviors associated with road rage, but there is one main deterrent: disengagement. Refusing to let one's own emotions dictate response to a real or perceived road incident is the best way to avoid initiation or escalation of dangerous driving situations with other motorists.

Factors That Contribute to Road Rage

Driving an automobile is inherently hazardous because of the many variables that are always at play, such as weather, traffic patterns and accidents, and the actions of other drivers. Some of those actions may be unintentional, such as swerving into another lane due to a momentary distraction, but others are deliberately intended to cause anger or even to do harm. That is the case with perpetrators of road rage. They let anger build within themselves until they make irrational driving decisions designed to retaliate against a perceived vehicular-related wrongdoing by another driver or individual.

While many drivers consider the act of driving to represent individual freedom, they often overlook the fact that driving is actually a communal activity. Drivers are rarely on the road by themselves, and thus participate in a larger driving community made up of diverse drivers with varying agendas, skills, distractions, and experiences. That disassociation with others while driving plays a part in the evolution of road rage. Drivers who focus solely on themselves may perceive another driver's actions only in terms of how it affects them individually, rather than the driving community as a whole. Believing that an action is directed personally makes it much easier for emotions to evolve into anger.

Cultural views about aggressive driving do not help. In the United States, children learn early on that the regular rules regarding accepted behaviors do not always apply in an automobile. Almost everyone at one time or another has engaged in, and thus demonstrated to others, some form of aggressive driving behavior, such as speeding or changing lanes multiple times to outpace traffic. Some movies and television shows also portray aggressive driving as a norm, or even as a positive and exciting undertaking.

Other cultural views also serve to feed road rage in the United States. For example, standing up to confrontation is perceived as a favorable and courageous act. In a territorial society that also encourages taking out one's frustrations to provide personal relief, the mix provides a hotbed for festering emotions. Those emotions occasionally erupt as road rage. Road rage incidents typically occur when drivers already under stress from something in their work or home life encounter a situation that

triggers an aggressive response that is often irrational and directed at another driver or individual.

In an already tense individual, driving can add even more pressure. For example, the restricted mobility of the driver's seat hampers physical movement, and the monotony of many roadways may only add to the driver's feelings of confinement and limitation.

In addition, the sense of unpredictability and having no control over certain events, including road work, weather delays, and the actions of other drivers, may increase driver anxiety and skew objectivity in favor of misinterpretation and overreaction. The scenario often perpetuates itself in one driver's negative reaction feeding another's until the cycle escalates into active aggression based on raw emotion rather than rational reasoning.

Behaviors Tied to Road Rage

Part of the issue in determining what constitutes road rage is the lack of clearly defined parameters. There is no consensus among the public and law enforcement agencies about behaviors that can be definitively called road rage. While some drivers classify honking the car horn or changing lanes without signaling to be aggressive driving, others do not. Similarly, some drivers consider driving 10 miles per hour over the speed limit to constitute aggressive driving, but law enforcement officials generally do not.

Broadly speaking, driving behaviors that stem from impatience or inattentiveness, such as not using a signal when turning or not stopping fully at a stop sign, represent the bottom tier of aggressive driving actions. Almost everyone perpetrates this type of behavior at some point during their time behind the wheel.

The sparks of road rage begin at the next tier of aggressive driving behavior, which involves maneuvers that specifically target another driver as part of a power play or act of retaliation against a perceived malicious act. These types of activities may include purposefully blocking another car from passing or slamming on one's brakes to force another car to react. It is usually the final stage before road rage. Road rage represents the escalation of the previous stage's feelings of righteousness and retaliation, and then combining them with acts of reckless driving, such as racing, and even actual violence, including chasing or threats with a weapon.

Dealing With Road Rage

Someone whose aggression has evolved toward road rage is likely to perceive even an inadvertent or nonexistent driving error as an act of aggression toward them, triggering a dangerous driving reaction. The best way to respond to another driver's rage is to remain in control of one's own emotions and one's own vehicle. Responding with a horn, a gesture, or increased speeds likely will serve only to aggravate an already tense situation. Failing to actively engage may quash potential danger and destruction. Preventing an incident from growing protects the safety not only of the potential victim but also the raging driver, the surrounding driving community, and any law enforcement personnel who may be called to the scene.

On the other side, drivers who find their feelings starting to build toward road rage can do their own part to stave off incidents by changing their attitude toward driving entitlement and focusing on better driving habits. Those habits include allowing oneself sufficient time to get from point A to point B, and accounting for the likelihood of minor traffic delays in advance.

All drivers should avoid distractions such as phone calls or intense concentration on a work or life problem. It is also important not to drive while physically fatigued, which makes every action more annoying and every response potentially more aggressive. When an irritating scenario does arise, drivers should resist any urge to pursue the situation or engage in any retaliatory measures. Basically, self-control is essential. It will help drivers make more rational and safer decisions in the heat of anger while on the road.

Road Rage Statistics

A study of nearly 4,000 U.S. workers conducted in May and June 2012 by Harris Interactive on behalf of the careers Web site CareerBuilder.com found that distracted and angry drivers are prevalent on the nation's highways during peak commuting drive times.

According to the survey, 58 percent of commuters said they have experienced road rage, either as a recipient or a perpetrator. Nearly one driver in 10 reported having become involved in an altercation with another commuter. Road rage incidents were found to be more common among commuters with longer drive times, although those with shorter

commutes also reported experiences associated with aggressive and dangerous driving.

Among respondents with a commuting duration of 10 minutes or less, 54 percent indicated that they had occasional experiences with road rage, as did 37 percent of drivers with a commute time of less than five minutes. Incidents were slightly more common among female drivers, with 61 percent admitting to a likelihood of feeling angry or aggressive while driving, compared with 56 percent of male respondents. Younger drivers, ages 25 to 35 years, were the most likely to experience road rage based on the survey's findings.

Geographically, a 2010 study on road rage conducted by Reuters determined that the U.S. cities with the most aggressive drivers were New York City, Dallas/Fort Worth, Detroit, Atlanta, and Minneapolis/St. Paul. The city with the most courteous drivers was Portland, Oregon, followed by Cleveland, Baltimore, Sacramento, and Pittsburgh.

The driver behavior cited by 84 percent of respondents as being the most irritating and likely to cause anger and road rage was seeing another driver talking on a cell phone. Some 50 percent of drivers also cited being cut off as an instigator of road rage. Other aggravating behaviors called out by respondents included motorists driving too fast, following too closely, eating behind the wheel, and texting.

More than one-quarter of the drivers polled also indicated that they had seen other drivers performing dangerous activities such as applying makeup, shaving, and reading while driving. Among the reported reactions to such behaviors was honking a horn (43 percent), cursing (36 percent), and making a rude or threatening gesture (10 to 13 percent).

Conclusion

All drivers are responsible for ensuring their own safety, the safety of their passengers, and—to the extent possible—the safety of others on the road. As such, it is important to recognize that road rage is a choice. While road rage is certainly fed by heated emotions and stressful situations, it is not an uncontrollable occurrence.

Drivers tempted or confronted by a potential road rage situation should be aware that a single aggressive act by just one driver can trigger a chain of escalating events that could lead to deadly consequences. Accidents caused by aggressive driving

account for more than half of all vehicular fatalities in the United States.

Road Signage

Signage has long been considered an effective means of human communication and cooperation. Signs provide a range of different types of information in a way common to all, irrespective of language. Signs and symbols can communicate, among other things, rules, instructions, dangers, feelings, origins, and identities. They capture situations and specific circumstances, educate, and notify or report information to the viewer. There are different types of signage, including private signage (used by those with property interests and landowners) and commercial signage (signs to advertise businesses and services), as well as statutory road signage.

History

The word *sign* derives from the ancient Latin word *signum*, meaning sign, indication, mark, or token. Signs have been used since prehistoric times, with the first cave paintings. Later, the Romans were erecting stone columns along the roadside throughout the Roman Empire. These columns had etched on them the distance and direction from that point on the road to Rome. The stone

columns, known as milestones, are the earliest road signs.

As the network of roads developed across Europe and overland trade between Europe, North Africa, Asia Minor, China, and India increased, the need for road signage grew. By the late Middle Ages, road signs were being used for more than one direction. Multidirectional road signage had been established at intersections across Europe by the late 1400s, indicating the direction to major towns and cities.

In the United Kingdom (UK), local parishes installed guide posts (often referred to as fingerposts). These posts had one or more arms, or “fingers,” which pointed in the direction of travel to named places and included (on the finger) the distance from the post to the destination. Made usually of cast iron or wood, the poles were painted with black lead-based paint and the fingers were white or gray with black letters.

While these guideposts were predominantly established for road users, there are examples of their use for inland waterway travel. In 1697, legislation was passed giving responsibility for the installation of fingerposts to local magistrates. This was followed by the introduction of the General Turnpike Act in 1773. This act required trustees of land to install their own signage marking distances and directions to towns (and usually to London).

It was not until the 19th century, with the advent of the bicycle and later the automobile, that the utility of road signs was recognized and their prominence increased. It was the Touring Club Ciclistico Italiano (TCCI), which later became the Italian Touring Club (hereafter referred to as the Club), that devised one of the first modern-day road sign systems in the world. Led by cycling enthusiast Luigi Vittorio Bertarelli until his death in 1926, the Club sought to promote travel and tourism by advocating measures to systematize traffic and improve road signs. The Club also published maps and guides on Italy and its regions to aid tourists and visitors.

In 1900, a Congress of the International League of Touring Organizations was held in Paris to review proposals for standardizing road signage. By 1908, the International Road Congress in Rome had established the patterns for the main traffic signs. This standardization was followed swiftly by a number of other European states that agreed on the use of certain pictorial symbols, including the

signs indicating a bump in the road, a bend, intersection, and grade-level railroad crossing. The use of symbols rather than words was considered easier to see and a more effective form of communicating information at both distance and speed.

Modern Signage

Signage on the UK road network conforms generally to European norms for prohibition signs, such as danger and caution being displayed with a red border rather than the customary yellow background in the United States. The main anomalies in the United Kingdom are the provision of distances shown in miles or yards and the speed in miles per hour (rather than kilometers), and the height and width restrictions shown in feet and inches.

The present nonmotorway road signs were reformed in 1964 under the Worboys Committee. They are governed by the Traffic Signs Regulations and General Directions (2002, SI 2002, No. 3113). This legislation and its amendments together specify the design requirements—including the size, color, and type—of all road signs conveying information or warning, requiring, restricting, prohibiting, or limiting the speed of vehicles.

Signs may be of an informative, warning, or instructional nature. Instructional signs are generally circular, warnings are triangular, and informative signs are rectangular or square. Primary routes are indicated by green directional and distance signs with yellow text, and secondary roads use black text on a white background.

The Anderson Committee established the UK's present-day motorway signage system of white text on a blue background in the late 1950s and early 1960s. These distinctive British road signs, designed by Margaret Calvert and Jock Kinneir, were determined through tests to be the clearest at distance and motorway speeds of travel. While at the time the main objective of the design was safety, not style, in 2011 the London Design Museum recognized the pioneering design achievements of these signs through the acquisition of an M1 sign and other British road signs.

In the United States, a similar movement petitioning for posting signs on key roadways began in 1899 with a group of car owners who met at the Waldorf Astoria in New York to form a car club. By 1905, car clubs across the country were installing signs on main roadways, designating routes, destinations,

and distances for motorists. The Buffalo Automobile Club was the first to put up a network of signs in New York, and by 1909, the Automobile Club of California had installed signs on major roadways within a 250-mile radius of San Francisco.

Standardization of road signs was adopted in the United States in the mid-1920s. An article published in October 1925 in the *American City Magazine* outlined the introduction of standardized road signs including, detail related to the shapes, sizes, and colors as adopted by the Joint Board on Interstate Highways. These standardized road signs fall into two groups: (1) the standard route markers and (2) the danger and caution signs. The standard route markers providing directional and information signs use the shape of the official U.S. shield (the six point shield). Originally made of steel, these signs have a white background with black type.

The approved design and information to be contained on the signs for U.S. highways was described in *American Highways* in April 1927 as the “commonly known U.S. shield outline, and this shield carries the route number, as well as the State name through which the road passes.” On the hand, signs indicating danger or caution are differentiated by degree of danger through sign shape, color, and marking.

The signs have a yellow background with black letters and/or symbols. For instance, a round sign will only be found at railroad crossings, an octagonal sign will be used where a complete stop is required, and the diamond shape indicates that there is some road condition ahead that calls for the exercise of caution. The use of shapes rather than just color is to enable those who may be unable to read or are color-blind to understand and take the necessary action. The road signage system emerging in the United States in the 1960s adopted many international symbols and pictorials depicting road conditions, speed limits, and other travel information, while at the same time developing its own design style. The yellow or white background colors for U.S. road signs were considered to provide the greatest contrast with black lettering, especially in low visibility and at night.

The material used for road signs has evolved along with the signage itself. Originally made from stone or wood, the 18th and 19th centuries introduced painted cast iron and steel. In the mid-20th century, sheet aluminum with adhesive plastic coatings

Hundreds of worn metal street signs in typical U.S. styles with yellow and white backgrounds and black lettering are set aside in a scrap pile in New Orleans, Louisiana, in 2011.

began to be widely used. In the United States at this time, glass beads were being used in some signs as a means of producing a reflectorized effect at night. These beads, approximately 0.75 inch in diameter, were glued onto the sign in the shape of numbers or symbols. The development of retroreflective sheeting increased sign visibility at night. This transparent reflective film is still used for road signs today.

A new generation of road signs and signals emerged with the development of light-emitting diode (LED) lighting. The road beacon system and electronic displays enable information provided to road users to vary to reflect the road conditions and circumstances. They use intelligent technology (IT) via sensors or remote controls. Information posted on these signs can change and often includes road closures, temporary speed restrictions, current average journey times, and notifications of accidents, as well as public safety information such as missing children alerts (Amber Alerts). These road signs dispense the latest information on mobile unit

or overhead boards in a convenient way that is visible to all road users and have led to improvements in road safety.

With growing volumes of traffic, higher speeds of vehicles, more commercial traffic, and an increasingly sophisticated road network, road signs must be effective, not only in communicating the distance to and direction of a destination for ease of navigation, but, more importantly, in reducing the risk of accidents. In order to achieve this, signage is a highly scientific and technical discipline grounded in the need to ensure signs are visible, intelligible, readable, understandable, and motivate the necessary behaviors in road users.

While countries may have created design differences within the development of their road signage systems, there exists a vast uniformity in the symbols adopted that communicate information to road users. This is of benefit to accident prevention and safety as the information is easily recognized, translated, and understood by travelers and tourists in an ever more accessible and transient world.

Road Surface Marking and Markers

"Road surface marking" refers to any type of apparatus or material used on the surface of a roadway or parking area as a means of communicating navigational, safety, and traffic enforcement messages to drivers and pedestrians. For example, road surface markings and markers are used to define lanes of traffic, deter excessive speed in certain areas, delineate pedestrian crossings, and designate parking spaces.

In the United States, the practice of road surface marking has evolved significantly from the first recorded use of a painted center line to designate lanes on a Michigan highway in 1911. Modern road surface markings incorporate the latest technological advances in terms of materials and application across all types of road surfaces throughout the country.

Most countries have their own road surface marking standards, and there is no uniformity across international borders. Broadly speaking, however, road surface markings worldwide fall into three main categories: mechanical markings, non-mechanical markings, and temporary markings.

Mechanical Road Surface Markers

Mechanical road surface markers are generally raised or recessed into the road surface and may be reflective. Most mechanical markers are permanently installed, although they can be moved or modified based on needs and capabilities. The main types of mechanical road surface markers in the United States are "Botts' dots" and rumble strips.

Botts' dots are named for the California engineer Elbert Botts, who invented the epoxy that keeps the raised white half-spheres secured to the road surface. Botts' dots are low to the ground and are non-reflective. They are used most frequently to delineate the edges of traffic lanes and are sometimes used across travel lanes to keep drivers' attention on the road. In addition, this type of road surface marker is used to make drivers aware of school zones, upcoming toll booths, and significant speed limit restrictions.

Because Botts' dots are raised off the road surface, they are not as suitable for road surface marking in regions where snow plows are used regularly

to scrape roadways for snow removal. Another marking device known as a “cat’s eye” takes snow plowing into account. It is made up of four reflective lenses mounted in a durable white rubber housing that is mounted into a cast-iron form. The rubber housing sinks into the form when a vehicle moves over it, providing a relatively smooth surface for plows to pass over. A self-cleaning mechanism wipes the lenses each time the device is depressed. This type of marker is used widely, but mainly in Great Britain and Ireland.

“Rumble strip” refers to a series of shallow channels that are ground out of the pavement on a roadway to create a vibration and intonation when a vehicle passes over it. The vibration and sound are intended to alert the driver about approaching hazards or areas that require reduced speed and caution. Raised strips that are adhered to the road surface serve a similar purpose, creating a vibration and sound when a vehicle passes over them to warn the driver.

Road surface markers that have reflective surfaces are commonly used as lane dividers and to indicate exit and on-ramp access roads. The incorporation of a raised retroreflective element into the marker makes it more easily visible in the dark and in inclement weather circumstances, such as driving rain or snow.

Reflective road markers in the United States tend to be installed to appear white to drivers proceeding in the proper direction and red to those who are traveling against the intended direction of traffic flow to provide an extra visual warning of potential danger.

Reflective markers, which are alternatively known as raised pavement markers or road studs, also can be used to identify the location of fire hydrants or other stationary resources for use by emergency service vehicles or to identify pedestrian crosswalks. In addition, reflective markers are occasionally used at the entrances to gated communities to indicate a barrier to through traffic or the site of a code-entry device to open the gate.

In colder climates subject to snow and regular road clearing, reflective markers are often installed below the road surface and appear as an elongated narrow triangle to drivers on the road. Technological advances have enabled raised reflective markers to be installed above the road surface by incorporating rails that protect the reflective

components of the marker from being damaged by the blades of snow plows.

Nonmechanical Road Surface Markers

In addition to mechanical road surface markings, which are typically raised or recessed from the driving surface of the road, several nonmechanical approaches exist that provide flexible, cost-effective options for marking road surfaces. The most widely used nonmechanical markers include the use of paint, plastics, thermoplastic binders, or epoxy.

Paint is a low-cost method for road surface marking. It is widely used to designate travel lanes, delineate the borders of parking spaces, and indicate loading zones. Sometimes an additive, such as tiny glass beads, is included in the paint to create a more reflective surface for better visibility. Painted markings are typically applied by a specialized “striper” truck that disseminates the paint in a controlled manner immediately following the laying of the pavement as part of road construction or maintenance. Symbols other than lines that are painted on roadways and parking lots, such as arrows indicating turn lanes and diamonds identifying high-occupancy-vehicle lanes, are usually applied manually using a stencil template.

Plastic tape, often embedded with reflective components, is another commonly used method for marking road surfaces. It functions as a strong, cost-effective material to mark pedestrian and railroad crossings, bicycle paths, and lanes dedicated for use by high-occupancy vehicles such as multiple-passenger commuter cars, taxis, and buses. The plastic tape can be adhered to the road surface using industrial-grade rubber cement, which lasts about three years, depending on the region.

For example, in areas where snow plows, salt, or sand are used to remove ice and snow from roadways, the tape and binding agent can wear more rapidly. Plastic tape also can be inlaid into the pavement itself using a heating and hardening process.

Thermoplastic road markers take the use of plastic-based markings one step further. Thermoplastic coatings are generally in the form of a dry mix comprised of binder resins, plasticizers, glass beads or other reflective components, white or yellow (and sometimes red) color pigments, and fillers.

They offer improved durability and sustained reflectivity compared to paint and plastic tape markings, but they require more up-front cost

A "Botts' dot," named for engineer Elbert Botts, is affixed to a road in Australia. Botts' dots are used to delineate traffic lanes, school zones, toll booth approaches, and speed limit changes.

and specially designed vehicles to heat and apply the thermoplastic mix to the road surface.

Initial reflectivity occurs at a second stage of application, when glass beads are embedded into the smoldering mix just after it is put on the road and before the plastic hardens. Long-term reflectivity takes place once the surface layer is worn off, uncovering the beads or other reflective component originally mixed in with the binder blend. Many common applications of thermoplastic road markers involve preformed and precut devices that are used to demarcate intersections, stop lines, crosswalks, and bicycle lanes. They also are used frequently to create directional arrows and access symbols.

Epoxy offers an affordable alternative to paint and plastics for use in road surface marking. It is created through a chemical process that results in a resin that reacts with certain chemicals to form a hardening or curing agent that is very strong and resistant to high temperatures, high traffic, and chemical degradation. When applied to road surfaces, epoxy provides durable striping.

Temporary Road Markers

Temporary road markers are used to supplement more permanent mechanical and nonmechanical markings. They are used largely for construction and maintenance activities or to indicate temporary traffic diversions necessitated by large public events, such as a marathon, or by safety situations resulting from accidents or flooding.

Temporary markers also can serve as placeholders for more permanent marking methods that will subsequently be applied or to alter traffic patterns that follow a consistent change schedule. For example, temporary road markers can be used to direct two-way traffic into a one-way pattern around a school to accommodate student drop-off and pick-up at specific times during the week.

Road surface markers that are temporary in nature include removable signage, pylons, and barricades. Sometimes paints and plastic tape are used for short-term road marking. Temporary road markers can be reflective or nonreflective, depending on needs.

Common U.S. Road Surface Markings

Standards for road surface marking in the United States are set and enforced by the U.S. Department of Transportation's Federal Highway Administration and are published in the *Manual on Uniform Traffic Control Devices*. While specific applications and materials for markings may vary by and within each state, white markings are generally used to indicate division of lanes in which traffic travels in the same direction, and yellow markings are used to signify separation of lanes in which traffic flows in the opposite direction on either side of the surface stripe.

A single dashed line is universally understood across the United States to mean that passing or changing lanes is permitted. A single solid stripe indicates strong discouragement for passing and changing lanes, while a double solid line signals that passing and changing lanes are legally prohibited. In cases where there is a double white line with one side featuring a solid stripe and the other side sporting a dashed line, the message for U.S. drivers is that passing is permitted from the lane of traffic with the dashed line but is not allowed from the lane on the side with the solid line.

Solid lines are also used to delineate the outside edge of the pavement from the shoulder of the road. Right-edge lines are marked with a solid white line

and should always be on the passenger side of the vehicle, while left-edge lines are marked with a solid yellow line and should be on the driver's side of the vehicle. A stop line is a wide white line that spans the applicable lanes perpendicular to traffic. Road surface markings for pedestrian crosswalks take the form of either two parallel solid white lines that cross the line of traffic on a roadway or two parallel solid white lines punctuated with perpendicular internal white stripes, which may be used on larger roads.

Roadside Assistance Programs

Despite escalating costs of fuel (gas prices nearly doubled in the first decade of the 21st century), the American transportation network is still defined largely by vehicular travel, and that travel system only works when vehicles are reliable and able to run. In a country with more than 250 million vehicles that travel on more than 4 million miles of roads, the possibility for unanticipated engine failure or catastrophic breakdowns along busy highways or in remote or unfamiliar areas exponentially increases. Given that current American Automobile

Association (AAA) data suggest that car owners are now more likely to hold on to older cars in the face of economic uncertainties (the average age of on-road vehicles in the United States is just over 11 years), vehicular breakdowns have become a significant concern and have occasioned, in the era of wireless communication, a wide range of cutting-edge, 24/7 roadside assistance programs designed to not only provide vehicle owners with speedy and reliable repair service but also help maintain unimpeded traffic flow critical to the nation's massive highway system.

The principle behind roadside assistance programs is simple—most car failures are caused by basic problems, many of them the consequence of bad luck or simple carelessness. These programs can be traced to the early 20th century. During the initial automobile craze, car owners, then relatively few, made up a kind of exclusive club in cities. There were few garages and even fewer mechanics. Car owners were often the best equipped to address car problems. As a consequence, they would maintain unofficial networks of close communication neighborhood to neighborhood (long-distance driving was still impractical). Owners would know each other and, should they be near a telephone, could summon help when their cars would suddenly stop or overheat or tires would blow out or if they simply got lost.

Postwar Growth

After World War II, as part of the massive suburban expansion when car usage spiked sharply, suburban commutes as well as interstate and even cross-country travel became the norm. Roadside assistance programs evolved to meet that challenge. But the operating concept of such programs was still simple enough: if the car problem was basic, get the car back on the road; if that was not possible, tow the car to the nearest available garage.

Rather than relying on informal Good Samaritan groups among a small coterie of car aficionados, now major companies, most prominently motor clubs/travel agencies such as AAA and insurance companies (most notably, in the beginning, Allstate) developed programs for which car owners could pay a set annual fee to insure that, in the event of any number of relatively minor roadside problems, assistance could be arranged quickly and safely. To accommodate the services, these same companies

pioneered placing emergency call boxes every few miles along the most heavily traveled roads.

Roadside assistance programs were never designed as part of any post-accident response, nor to assist in the event of medical emergencies involving the driver or passengers. Rather, they dealt with a range of vehicular problems. As these programs developed, the kinds of problems covered grew as companies vied for the steadily increasing market of vehicle owners during the 1960s when America's love of the automobile flourished in the age of cheap gas. Although initially most roadside assistance programs simply provided help for motorists stranded with a dead battery or a flat tire, over time the programs also offered services for cars that had run out of gas (delivering up to three gallons) and/or engines that needed critical engine coolants or motor oil.

Services were extended to help retrieve keys from locked cars. In wintry weather, roadside assistance programs would offer to pull out vehicles stranded in snowbanks. Insurance agencies described such events as both unanticipated and inevitable, whatever the diligence and care of the driver. In each case, the critical work could be done right off the highway—only in extreme circumstances would the car need to be towed, as that would most likely strand the owner. In such cases, many of the programs provided help in finding hotel accommodations and, in the most extreme cases, help in securing alternate transportation.

Unlike far more expensive comprehensive breakdown recovery programs, insurance programs geared to assist in towing cars with catastrophic engine failure as quickly as possible to a garage (the preferred roadside assistance programs in the United Kingdom and in Europe, where highway transportation is far faster and more dangerous than in the United States), roadside assistance programs are geared to help with problems that, while not critical, are nevertheless vital to the car's operation. Roadside assistance programs can assist drivers who are still in their driveways.

Given that relatively rare instances of simple bad luck or embarrassing recklessness are chiefly responsible for most roadside assistance program incidents, drivers buy into the coverage—usually an annual fee somewhere between \$35 and \$100 depending on the range of services covered—essentially for peace of mind. AAA data indicates that in

2012, for instance, less than 28 percent of those with roadside assistance coverage actually used it. But programs have proliferated. Over the last generation, roadside assistance programs have been developed not only by insurance providers and travel agencies but also by car manufacturers who provide programs for new car owners as part of purchase incentive packages. Oil companies and service plazas advertise roadside assistance programs. Even credit card companies and cell phone providers use roadside assistance packages to attract customers.

In 2012, Walmart introduced a modified program as part of its garage service. In many rural areas, church groups and other volunteer civic organizations do the work of roadside assistance, their services advertised on billboards and through Internet information services. The revolution in wireless communication systems has created an entirely new generation of roadside assistance software—OnStar, for instance, can provide garages within the calling range the exact location of a stranded car. Roadside assistance programs now extend to RVs, motorcycles, watercraft, and even bicycles. Data collected by AAA suggest that more than three-quarters of car owners who must drive more than 150 miles a week have some form of roadside assistance insurance.

Criticisms

Given the wide range of highway systems and given the sheer number of vehicles prone to needing assistance around the clock and given the wide array of businesses offering variations of roadside assistance, the service is not uniformly efficient. In theory, the roadside assistance program chosen by the driver provides a toll-free number from which, in turn, local emergency field representatives would be dispatched in a timely fashion. Customer service online review forums, however, are replete with alarming stories of wait times for emergency assistance vehicles that often extend for hours, leaving the driver stranded in unfamiliar environments and compelling them ultimately to use their cell phone to arrange alternative help.

Professional garage mechanics are quick to point out that given the kind of cut-rate speedy service offered, it is not unusual for unscrupulous assistance providers to take advantage of drivers in dire circumstances. Representatives dispatched to the site often lack critical engine knowledge and repair

skills (and sophisticated mobile engine malfunction diagnosis equipment) to work efficiently with modern engines that are often delicately set to computer-driven systems. The “repair” they offer is at best a temporary fix that can give false reassurance to the vehicle owner, as the on-site mechanics are unwilling (or unable) to perform deep engine diagnoses such as checking the belts or tire pressure, making electrical repairs, testing air cooling systems, or analyzing brakes—the kind of checks done routinely in a full garage tune-up. Rather, now as a first resort, they tow because that is the easiest response. Towing itself, of course, puts enormous additional strain on a vehicle.

Conclusion

But even with those caveats, given the tight monitoring by travel agencies and insurance providers inevitable in a very competitive market susceptible to online reviews, roadside assistance programs are still one of the most notable achievements of the automobile age. Of course, the simplest way to avoid requiring roadside assistance is to be careful and to follow basic maintenance schedules suggested by car manufacturers. Despite the increasingly sophisticated computer-driven technologies in car engines, the problems addressed by roadside assistance are largely basic car upkeep procedures, although insurance providers point to other factors, including poor driving habits, ill-advised driving risks, the use of cheap fuel, and the owner’s failure to heed warning lights on the dashboard that track critical engine requirements (oil and coolant as well as tire pressure). Until cars do not require owner effort to maintain operation, participation in roadside assistance programs is viewed as not only essential but common sense.

Roundabouts and Traffic Circles

A roundabout is a refinement of a street pattern called the traffic circle or rotary. Both traffic circles and roundabouts are replacements for a traditional intersection and force traffic to move in a circular pattern, while allowing drivers to make a turn onto another street or continue on the same street from which they entered the intersection. Traffic circles have been in use since at least the early 20th century, while roundabouts were developed in the 1960s to overcome some of the problems with traffic circles. Roundabouts have been shown to reduce traffic speeds and accidents as compared to traditional intersections and tend to become popular once people become accustomed to them.

History

The first traffic circle in the United States was constructed in New York City in 1905. Located at the southwest edge of Central Park in Manhattan and designed by William Phelps Eno, it features a large monument to Christopher Columbus in the center of the circle and hence is called Columbus Circle. Many similar, large-scale circles (often with a diameter of more than 300 feet) were constructed in other U.S. and European cities, but they proved to have several problems that made them fall out of favor by the 1950s. In these early traffic circles, entering vehicles had the right of way, and this encouraged people to drive at high speeds (often above 30 mph) in the circle, leading to frequent high-speed collisions. In addition, the circles tended to become congested, so that they sometimes impeded the flow of traffic rather than facilitating it.

In the United Kingdom (UK), a rules change in 1966 that gave priority to vehicles already in the circle acted to reduce recurrence of both of these problems—requiring vehicles entering the

traffic circle to yield to those already in it discouraged high-speed entry and reduced the number of crashes, and also helped reduce congestion within the circle by forcing vehicles to wait for gaps in traffic before they could enter. At about the same time, traffic engineers began designing smaller traffic circles, called roundabouts, that also required entering and circulating vehicles to travel more slowly. These improvements in safety made the roundabout a popular intersection design adopted all over the world, although the United States is a fairly late adopter of this design.

Design

Although each roundabout should be designed to meet the needs of a specific situation, taking into account factors such as the volume of traffic expected, the size of vehicles expected to use the roundabout (for example, buses, semi-trailers) and the amount of space available, there are certain commonalities to each roundabout. A typical roundabout replaces an intersection, so multiple roads will approach the roundabout. Around the point where the roads would otherwise intersect, there is a large circular traffic island, often landscaped to alert drivers to the existence of the roundabout. Surrounding this island is a circular roadway; traffic moves in a counterclockwise direction in right-drive countries like the United States, and in a clockwise direction in left-drive regions like the UK.

Each of the roads will have a splitter island (separator island) or median dividing traffic into entry and exit lanes and alerting drivers to the existence of the roundabout. Exit lanes are typically wider than entry lanes to minimize congestion from cars slowing to exit, although this must be balanced against the need for pedestrian access and safety. If truck use is anticipated, the central island usually includes a traversable truck apron, a wide, sloped and slightly raised (for example, 2 to 3 inches off the ground) ring around the island to give trucks additional road space, while being sufficiently elevated to discourage cars from using it.

Pedestrian crosswalks are usually located so that they cross the roads leading into and from the roundabout at least 20 feet upstream of the entrance, to discourage vehicles from blocking the crosswalk while waiting to enter the roundabout. To facilitate wheelchair access, the curbs should have

sidewalk ramps, and the splitter islands should be cut through at the same width as the crosswalk; this last feature provides guidance to people with visual difficulties as well. Planters, railings, and other features can also help orient both sighted and visually impaired pedestrians to the location of the crosswalk. The slower (12 to 20 mph) speeds typical of traffic in a roundabout are similar to typical speeds of bicycle travel, so bicycles can use a roundabout similarly to automobiles.

Advantages and Disadvantages

The most important advantage of roundabouts is safety. A recent study by the Insurance Institute for Highway Safety (IIHS) of intersections where traffic lights and stop signs had been replaced by roundabouts found that the roundabouts showed a reduction of 37 percent for overall collisions, 40 percent for pedestrian collisions, 75 percent for injury collisions, and 90 percent for fatal collisions. Notably, the greatest reductions were for the most serious collisions, a result attributed to reduced driver speed upon entry to the roundabout, the necessity to yield to traffic already in the roundabout, and the lack of possibility for head-on, left-turn (right-turn in left-drive countries) and “T-bone” or right-angle collisions, because the traffic pattern never presents the conditions for those types of collisions.

The fact that traffic flow is continuous and there are no traffic lights also means that there is no incentive to speed up, as drivers often do when approaching a traditional intersection in order to “beat the light,” a behavior that not only increases the vehicle’s speed but also takes the driver’s attention away from the traffic conditions.

Roundabouts are also an efficient way to move traffic, because they promote a continuous flow rather than requiring one lane of traffic to stop even if there is no cross-traffic, as traffic signals and stop signs do. A study by researchers from Kansas State University found that in comparing traffic flow at intersections before and after installation of a roundabout, delays were reduced 20 percent with the roundabout as compared to the traditional intersection. Other studies by the IIHS found reductions of 56 percent in vehicle stops and 89 percent in delays.

Roundabouts have several other advantages as well. Unlike traffic lights, they function equally well if there is an interruption in power, as often happens after a weather emergency, because the

Columbus Circle in New York City, seen through a window in the Time Warner Center, was the first traffic circle in the United States when it was built in 1905. Early traffic circles like this one led to speeding and numerous accidents when drivers had the right of way upon entering the circle. Rule changes giving drivers already in the circle the right of way helped reduce these accidents, as did new designs for smaller circles, known as roundabouts.

traffic is controlled by driver behavior rather than by traffic lights. Roundabouts are also less expensive than traffic signals, because while both options have similar costs of installation, a traffic signal typically costs \$5,000 to \$10,000 per year in electricity and maintenance, while a roundabout incurs neither of these expenses. A roundabout may also have a smaller footprint, because although the traffic circle is often larger than a typical intersection, the reduction in delays and vehicle stops may mean that fewer traffic lanes are required leading up to the roundabout as opposed to leading up to a traditional intersection.

The principal disadvantage of roundabouts is that many people, particularly in the United States, are unfamiliar with them and do not know how to use them safely. Because roundabouts came fairly late to U.S. traffic engineering, and are not used in all

parts of the country, many people did not encounter a roundabout when they were learning to drive and may be anxious or resistant when encountering them. This means that when roundabouts are being added to traffic patterns, public education is necessary to familiarize people with this design and to teach them how to drive safely in roundabouts.

Another disadvantage is that roundabouts do not provide the aural cues many visually impaired people use to determine when it is safe to cross the street. Because traffic never ceases, and there are no traffic signals, it may be difficult to know when the road is clear and it is safe to cross. Unfortunately, drivers do not always yield to pedestrians, not even blind pedestrians.

Route Assignment Models

Route assignment, also commonly referred to as traffic assignment or route choice, is the problem of allocating a given set of trips (commonly referred to as demand) to a specific transport network or system (referred to as supply). The input required for the route assignment is comprised of

the supply (a complete description of the transportation system) and the demand (a matrix of interzonal trip movements, known as an origin-destination, or OD, matrix).

The output of a route assignment process is comprised of the allocation of vehicle volumes and costs (mainly in the form of travel times) on each link (defined as the connection of nodes within a transport network), under equilibrium conditions. Various models have been developed for solving the spatial distribution of trips in the network in order to achieve equilibrium.

Route assignment is the fourth step of the four-step conventional forecasting model. The first three steps are trip generation, trip distribution, and mode choice. Trips' origins and destinations are generated in the first and second step, respectively, while the mode with which each trip is conducted is estimated in the third step. Once the origin, the destination, and the mode are chosen, the routes followed by the users traveling in a transport network are calculated in the fourth step, solving the so-called traffic assignment problem (TAP).

Definitions of Network Equilibrium

The first reference to minimizing individual travel times was stated in 1841, but it was not until the late 1910s, when the subject of route choice over a two-route road network was examined. In 1924, the economist Frank Knight developed the argument that forms the basis of traffic equilibrium: he presented two highways connecting two terminals, one broad enough to accommodate a large number of vehicles but poorly graded and surfaced, and the second one with much better quality but with limited capacity. He stated that the trucks operating between the two terminals will tend to distribute themselves between both roads in such proportions that the cost per unit of transportation will be the same for all trucks on both routes. He concluded that the congestion created in the road with the limited capacity will reach the level at which both roads will be equally profitable.

In 1951, John Nash published the expected flow of traffic in a network, using the Nash equilibrium concept he developed within the game theory framework. He proved the existence and uniqueness of the equilibrium solutions.

In 1952, John Glen Wardrop stated two formal principles of the concept of equilibrium:

- *First principle.* The journey times on all the routes actually used are equal, and less than those that would be experienced by a single vehicle on any unused route.
- *Second principle.* At equilibrium, the average journey time is at minimum.

Various alternative definitions have been presented for the first principle. Let r and s be two different used routes in OD pair (p, q) , let h be the path-flow vector that contains the flow on each path for all the OD pairs, let D_{rs} be a path-shifting flow vector of the same dimension as h , which is zero in every position except those corresponding to the routes r and s , where the values of the vector are minus 1 and 1, respectively.

Equilibrium. The flow is a Wardrop equilibrium if, for each driver, the present cost on any alternative route is at least as great as the cost on his/her present route:

$$(C_{pqr}(h) \leq C_{pqs}(h)).$$

User-optimized. The flow is user-optimized if any driver who changes to an alternative route will experience a cost that is at least as great as the old one on his/her old route:

$$(C_{pqr}h \leq C_{pqs}h + \epsilon D_{rs} \forall \epsilon \in (0, h_{pqr})).$$

Equilibrated. The flow is equilibrated if any driver who changes to an alternative route will experience a cost that is at least as great as the new one on his/her old route:

$$(C_{pqr}(h + \epsilon D_{rs}) \leq C_{pqs}(h)).$$

The difference between user-optimized and equilibrated flows is characterized by the perception of cost by drivers. In the first definition, each driver is continuously aware of the cost on all routes, while in the second definition, the driver has only the information related to his own experience.

The current definition of network equilibrium was redefined in 1969, when researchers used the terms *user-optimized* (UO, or user equilibrium, UE) and *system-optimizing* (SO) to describe Wardrop's first and second principles, respectively.

These two principles have been used by all authors dealing with traffic assignment. The properties of equilibria have been reformulated as variational inequality problems, nonlinear complementarity problems, and fixed-point problems.

Definition of TAP

The problem addressed in traffic assignment is to allocate the OD flows to various routes according to the hypothesis that users try to minimize their travel cost, and making the assumption that the cost of each link is known in advance by all users. Two problems can arise in the TAP, depending on the Wardrop equilibrium definition adopted, either the system optimum TAP or the user equilibrium TAP. The second one is the most commonly used by transport planners and managers. The formal mathematical formulation is the following:

Consider a road network consisting of nodes $i \in N$ and links $a = (i, j)$. The set of origin nodes is P and the set of destination nodes is Q . Origin-destination (OD) flows between pairs of nodes are represented by dpq , where $pq \in C$ is the set of origin-destination pairs. A link flow from node i to node j is designated by fij and a link flow specific to a given origin-destination flow from p to q is designated $fijpq$. Accordingly, $fij = (pq \in C)fijpq$.

Conservation of flows of vehicles through nodes of the network is specified by three cases, depending upon whether the node is an origin $p \in P$, a destination $q \in Q$, or a simple intersection $i \in N$ of links:

$$\begin{aligned} j \in A_p f_{ijpq} - h \in B_p f_{hijpq} &= +dpq, \forall p \in P \\ j \in A_q f_{ijpq} - h \in B_q f_{hijpq} &= -dpq, \forall q \in Q \\ j \in A_i f_{ijpq} - h \in B_i f_{hijpq} &= 0, \forall i \in N \end{aligned}$$

where A_i is the set of nodes connected by links pointing out of i (after i), and B_i is the set of nodes connected by links pointing into node i (before i).

The first condition states that the net outflow at node p , which corresponds to the total flow from p to q , must equal $+dpq$. Likewise, the net outflow at node q , which corresponds to the negative of the total flow from p to q , must equal minus dpq . For all other nodes, total inflow equals total outflow.

The OD flow dpq , or demand from p to q , is determined by a function $dpq = gpq(tpq)$, which is assumed to be positive and strictly decreasing, and therefore is invertible, so that $tpq = gpq^{-1}(dpq)$, where tpq is the minimal route travel time from

origin p to destination q . The link travel time $t_{ij}(f_{ij})$ is a nondecreasing function of the link's own flow f_{ij} . Given this description of OD flows, the authors proposed to maximize the following function:

$$pq \in C_0 dpqgpq - 1 sds - ij \in A_0 f_{ij} t_{ij} sds$$

Or, to minimize the following function,

$$\begin{aligned} \text{Min } z &= \sum_{a \in A} f_a c_a w_d, \\ f_a &= \sum_{r,s} p_{rs} \delta_{a,rs} \quad \forall a \in A, \\ p_{rs} &= q_{rs} \quad \forall r \in R, s \in S, \\ h_{rs} &\geq 0, \\ \delta_{a,rs} &= 1, \text{ if a path } p \text{ passes arc } a, 0, \text{ otherwise} \\ \text{where,} \\ A, R, S &\quad \text{network's arc, origins and} \\ &\quad \text{destinations respectively} \\ Z &\quad \text{the value of the objective function} \\ f_a &\quad \text{total flow on arc } a \\ C_a f_a &\quad \text{cost of traveling arc } a \text{ when it} \\ &\quad \text{carries flow } f_a \\ h_{rs} &\quad \text{flow on path } p \text{ from origin } r \text{ to} \\ &\quad \text{destination } s \\ q_{rs} &\quad \text{demand on pair } rs \end{aligned}$$

Models for the Route Assignment

Two approaches for solving the route assignment or TAP were proposed during the 1950s: diversion curve assignment between two possible paths, and all-or-nothing assignment. The first method shifts the traffic to various paths, while the second method assigns all the interzonal traffic to the shortest path.

After the formal introduction of network equilibrium by Wardrop, various models have been developed for achieving equilibrium. W. Prager described in 1954 a formulation of the network equilibrium problem using a linear function for the estimation of the link travel time, and describing equal journey times of routes in terms of the differences in potentials at nodes of the networks, but without clarifying the source of the flows.

A. Charnes and W. Cooper proposed in 1958 a traffic network equilibrium formulation for the case of fixed origin-destination flows, but without specifying any actual impedance function.

M. Beckmann, C. B. McGuire, and C. B. Winsten proposed in 1956 the first constrained convex optimization formulation for the user-equilibrium assignment problem with elastic demand, considering the number of trips between each zone to be a

function of the travel time. They presented the first complete mathematical formulation of the first Wardrop's using link cost functions that increase with the flow on the links. They demonstrated that maximizing this function with respect to the demand and the flows, and subject to the above constraints, then, all used routes from node p to node q will have equal travel times, and no unused route will have a lower travel time.

M. Frank and P. Wolfe developed in 1956 an algorithm for solving quadratic programming problems with linear constraints. They proposed an iterative procedure, where in each iteration a sub problem was solved: the minimization of the linearized objective function by assigning all traffic to minimum-cost routes where link costs were determined by the link flows of the current solution of the main problem.

The new solution of the main problem was obtained by minimizing the original objective function by using a linear combination of the current solution and the solution of the subproblem. Since the objective function was evaluated using aggregated link flows only, path-based information was not available. The representation of the solution was link-based, resulting in low memory requirements, which is the main advantage of the method. The main drawback of the method is the slow convergence rate. The first application of a method for solving the route assignment problem was the route-based method proposed by S. Dafermos in 1968 and implemented by Gibert in the same year. In this method, flows are shifted from the maximum-cost route to the minimum one for each OD pair until both routes have the same cost.

L. J. LeBlanc, E. K. Morlok, and W. P. Pierskalla proposed the use of the Frank and Wolfe algorithm for solving the formulation proposed by Beckmann, McGuire, and Winsten, and tested it by using the traffic networks of Sioux Falls, South Dakota, which became an internationally well-known network for testing and benchmarking solution algorithms.

L. Dickson stated in 1977 the Wardrop's criteria as the finite-dimensional variational inequality problem below.

$$F x^* T \cdot x - x^* \geq 0, \forall x \in K,$$

where F is a given continuous function from K to R^n , K is a given closed convex set, and the objective is to determine $x^* \in K \subset R^n$.

Table 1 Link-, path-, and origin-based and LUCE algorithms

Link Based	Path Based	Origin Based
Decision variable		
Link flow	Path flow	Origin-based link flow
Information		
Minimum	Richest	Richest
Memory requirement		
Lowest	Highest	Medium
Convergence speed		
Low	Fast	Fast
Main categories		
Frank-Wolfe algorithm (Frank and Wolfe, 1956) Improved FW algorithms (Powell and Sheffi, 1982; Fukushima, 1984; Weintraub et al., 1985; LeBlanc et al., 1985; Lupi, 1986; Florian et al., 1987; Arezki, 1987; Arezki and Van liet, 1990; Daneva, 2003.) (RSD) Restricted Simplicial Decomposition algorithm (Hearn et al., 1985) (NSD) Nonlinear Simplicial Decomposition (Larsson and Patriksson, 1997)	(DSD) Disaggregate Simplicial Decomposition algorithms (Larsson and Patriksson, 1992) (GP) Gradient Projection algorithm (Jayakrishnan et al., 1994; Sun et al., 1996; Chen et al., 2002)	(OBA) Origin-based Algorithm (Bar-Gera, 1999, 2002) (NOB) Improved Origin-based Algorithm (Nie, 2008) Algorithm B (Dial, 1999,2006) (TAPAS) Traffic Assignment by Paired Alternative Segments (Bar-Gera and Luzon, 2007)
Observations		
The latest Conjugate/Bi-Conjugate FW algorithms appear comparable with origin-based algorithm in speed and accuracy.	Gradient Projection algorithm shows more advantages in small to medium-sized networks.	Algorithm B and TAPAS show much better performance than Bar-Gera's origin-based algorithm.

Dafermos proposed in 1980 a computational algorithm based in these variational inequalities. Smith presented in 1984 an alternative formulation of TAP, based in variational inequalities and formally proved the existence, uniqueness, and stability of the solution.

Y. Sheffi presented in 1985 a fundamental traffic assignment methodology, and the current formulation for the UE and the SO TAP.

UE: $\min x = a_0 x + a_w d_w$

SO: $\min x = a x + a_t(x)$

$k f_{krs} = q_{rs} \forall r, s$

$f_{krs} \geq 0, \forall k, r, s$

$x_a = r s k f_{krs} \delta_a, krs \forall a$

where,

q_{rs} is the OD matrix

x_a and t_a flow and travel time in link a respectively

f_{krs} the flow from r to s on path k

R. Jayakrishnan, W. T. Tsai, and J. N. Prashker introduced in 1994 the path-based algorithm, using the gradient projection in order to find the minimum of a Newton approximation of a transformed objective function. The gradient direction is calculated with respect to the flows on the non-shortest

paths while the step is found using second derivatives with respect to these flows, converging 10 times faster than the Frank and Wolfe algorithm. The drawback of this method is the large memory requirements for storing all the used paths.

R. Dial proposed in 2006 a path-based methodology for solving TAP, which eliminated the need for path storage, called Algorithm B. M. Florian presented in 2009 a revised version of the projected gradient method for equilibrium originally proposed by Jayakrishnan.

H. Bar-Gera proposed in 2002 the origin-based algorithm, where he defined the variables as an intermediate way between links and paths. He stated that the equilibrium of each origin is an acyclic graph, restricting the solution space to acyclic routes. This new methodology reduced significantly the computational effort, keeping the memory requirements to an intermediate level between the link-based and the path-based algorithms.

G. Gentile presented in 2009 a new algorithm named linear user cost equilibrium (LUCE), which achieves a very high convergence speed, because it assigns the demand flow of each OD pair on several paths at once instead of the all-or-nothing assignment used in all the other methods.

Comparison of Link-, Path-, and Origin-Based and LUCE Algorithms

The link-based algorithms use the conventional Frank-Wolfe method, which has been developed for solving linearly constrained quadratic programming problems, for solving the TAP optimization problem, with convex objective function and linear constraints. They iteratively reduce the gap between the best found lower bound and the upper bound from the last iteration until the stopping criteria are satisfied. Various improvements have been proposed for increasing the performance of the Frank-Wolfe algorithm, such as modifications in the step size or the search direction.

The path-based algorithms use the gradient projection algorithm used in computer communication networks. In this kind of network, path-flow solutions are essential for optimal flow routing, but they are usually smaller, being much more efficient than path enumeration in the road networks. The direction of search in the minimum of a Newton approximation of a transformed objective function, which includes the demand constraints,

is the non-negative constraint, the only one to be respected.

The origin-based algorithms consider flows from each origin separately, interacting on the network through mutual congestion effects. The algorithm splits the problem into the selection of the used links and the quantification of the flow assigned to each link. Table 1 presents the most significant insights of each type of model, as well as the developed models of each category.

The LUCE algorithm solves a deterministic equilibrium for the local route choice of users directed toward the same direction in each node for defining the descent direction search, instead of solving multiple shortest-path problems. The network is loaded through the corresponding splitting rates, avoiding explicit path enumeration, and assigning the flow of each OD pair to various paths at once.

Rural Transportation Mobility

For many Americans, transportation—whether to work, medical appointments, shopping, or visiting friends and family—is given little to no special

consideration because more than 90 percent of Americans own at least one car, with 85 percent traveling by car to work each day. This is slowly changing as car-owning city dwellers forgo automobiles in favor of mass transit or car sharing. Nevertheless, privately owned automobiles continue to reign as king among transportation options.

Public transportation consists of a variety of modes, including buses, trolleys and light rail, subways, commuter trains, high-speed rail, streetcars, cable cars, van pool services, paratransit services for seniors and people with disabilities, ferries and water taxis, and monorails. In 2011, public transportation ridership was at its second-highest peak in 56 years, with 10.4 billion rides. Use of public transportation is not a new idea, but one that is gaining in popularity despite the stigma that public transit is the mode of transportation for the poor. This stigma is largely a result of a lack of clean and efficient public transit systems in the United States. Those with the financial means to avoid waiting in lines, sitting in crowded vehicles, and facing a perceived risk of assault often opt to transport themselves.

Approximately 15 percent of urban dwellers (nearly 8.3 million people) are classified as poor, as opposed to 7 percent of suburbanites. The prevalence of urban poverty is largely a result of the availability of public transportation: many poor people remain in urban centers because of the availability of public transit, which enables people who do not own a vehicle to work, shop, and access services. Their mobility out of the range of public transit routes is limited. But what of the rural poor, more than 8.5 million people, who live outside metropolitan areas?

Precarious Situation of the Rural Poor

Although poverty rates per square mile tend to be higher in urban areas due to higher population density, rural America contains more people in poverty. Many impoverished people in rural areas do not own automobiles, and the lack of public transportation severely limits their upward mobility. Nearly 70 percent of rural residents live in communities with little or no public transportation opportunities. Given the low population density, busing and rail become difficult if not impossible viable transportation options when people are far from would-be transportation hubs. Low personal-vehicle

ownership combined with low population density and disparate destination points for employment make it difficult to coordinate routes, and transportation becomes largely cost-prohibitive.

Rural transit has not only been found to be cost-effective, providing three times the benefit per cost, on average, but it can save federal and state governments money in the long run. When rural residents are able to access jobs, education, and child care, fewer residents are reliant upon social programs such as Temporary Assistance for Needy Families (TANF), Medicaid, and unemployment compensation. Families in rural areas are more often in need of social services and are more likely to be disabled or elderly than are their urban counterparts.

Nearly 90 percent of the counties in which poverty has persisted for several decades are in rural areas. Child poverty is particularly pronounced, and in 2006, 20 percent of rural residents had one or more disabilities, compared with 14 percent of urban residents. Despite the high level of need, rural families are less likely to use government support programs. Social service programs that are used struggle to serve all who reach out for help.

Access to Social Services

Despite their larger land mass, rural areas have a smaller tax base with which to work. This lower tax base, which means lower available funds for the public good, affects the availability of infrastructure, including social services and transportation to those services. Rural areas are also less likely than urban areas to benefit from philanthropic support to fund social services such as job training and mental health services. With families in rural areas often living many miles from the nearest town, limited transportation further distances the rural poor from government services and programs designed to help reduce poverty. Less than 10 percent of federal dollars allocated to public transportation goes to rural communities.

In reaction to the challenges of rural poverty and transportation, the U.S. government created a variety of grants to assist rural communities with transportation needs. Among these was the Job Access and Reverse Commute (JARC) program, administered by the U.S. Department of Transportation (DOT), with the purpose of transporting low-income residents and TANF recipients to jobs, training, school, and other social services, as well

as supplementing transportation services for health care and child support.

However, providing transportation service in rural (non-metro) areas can be cost-prohibitive because of the lack of population density and large distances to be covered. JARC authorized up to \$150 million per year for new or expanded transportation services while being funded through TAE-21 (the Transportation Equity Act for the 21st Century), which expired in 2003. Under SAFETEA-LU (Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users), JARC was authorized to spend \$165 million in 2009, only 20 percent of which was made available to rural communities. The funding for SAFETEA-LU expired June 30, 2012.

Rural Public Transit

Rural public transit, the equivalent of urban bus lines, provides transportation to the elderly, people with disabilities, and human services recipients. However, this form of public transportation is available to only approximately half of all rural counties nationwide. Of these, few are found in the most rural, isolated areas.

Established in 2004, the Federal Coordinating Council for Access and Mobility (CCAM) manages more than 60 programs that provide funds to transportation-challenged communities, with a priority of expanding the coordinated human services transportation infrastructure, also referred to as the United We Ride initiative.

Programs that support the purchase of vehicles for community transportation services include Community Development Block Grants (CDBG) from the U.S. Department of Housing and Urban Development (HUD) and Safe Transportation Funds from the Federal Highway Administration. Financial support of transportation facilities can be found through the U.S. Department of Agriculture's (USDA's) Intermediary Funding Program and the Federal Transit Administration's (FTA's) Non-urbanized Area Formula Transit Grants, alternately referred to as Section 5311 Grants. Typically ranging from one to 50 vehicles, 5311 transit systems are county based and are generally found in the more populated rural areas.

Tribal Transit

The vast majority of Native American and Alaska Native reservations are rural; only 10 tribes live in

metropolitan areas. Although poverty among rural Americans is generally higher than among urban or suburban dwellers, the poverty rate on reservations is approximately double (over 32 percent).

Since 2005 the FTA's 5311(c) Tribal Transit Program has distributed \$60 million to federally recognized tribes and Alaska Natives in rural areas, in addition to \$17 million of stimulus money in 2009 from the American Recovery and Reinvestment Act (ARRA), to plan, start, and enhance local transit services. Of the nation's 564 recognized tribes, 101 received transportation funding, a substantial increase from the 18 tribes that received transit funding from the FTA in 1999.

Despite the increase in funding, for future sustainability the National Congress of American Indians and the Intertribal Transportation Association's Joint Task Force on Tribal Transportation have urged Congress to further increase funding to at least \$15 million per year in the next federal highway bill.

Several factors indicate that an additional \$15 million per year would be insufficient to sustain the current growth of tribal transit. In 2010, over one-third of the applications to plan, build, and sustain transit were denied due to lack of funds. Inflation and fuel costs further increase start-up and operational costs for transit services. Budgets will also increase as the number of operators and riders increases.

Conclusion

Rural transportation benefits not only individuals but also the community as a whole. Access to transportation can bring new customers and tourists to rural towns, reduce congestion for those commuting to highly trafficked areas, and increase access to human services agencies and the services they provide.

Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users

The Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) was the federal surface transportation reauthorization legislation signed into law in August 2005, after nearly two years of Congressional debate and 12 short-term extensions of SAFETEA-LU's predecessor, the Transportation Equity Act for the 21st Century (TEA-21).

SAFETEA-LU guaranteed \$244.1 billion funding for highways, highway safety, and public transportation for fiscal years 2005 to 2009, but analysts most often cite \$286.5 billion by including fiscal year 2004 funding (entirely covered by extension acts) to get a figure directly comparable to the six-year figures for the preceding transportation funding bills, the Intermodal Surface Transportation Efficiency Act (ISTEA) and TEA-21.

More evolutionary than revolutionary, SAFETEA-LU retained much of the core structure from ISTEA and TEA-21, but key changes included establishing a new core program for highway safety, updating several programs and planning processes, expanding

options for tolling and financing through public-private partnerships, and creating several programs to demonstrate new transportation technologies and study the future of transportation.

The Legislative and Political Process

As with TEA-21, the two major debates concerning SAFETEA-LU were the total size of federal funding and how to distribute that funding among the states. Donor states, mostly fast-growing southern states, wanted the TEA-21 guarantee of 90.5 percent return from funds contributed to the Highway Trust Fund (HTF) increased to 95 percent. Donee states generally had no problem with this as long as their funding was not cut. Many members of Congress wanted to increase the overall size of the bill substantially so that it would provide adequate funding for both donor and donee states. However, this was impractical without increasing the gas tax or adding general fund revenues, both measures President George W. Bush's administration was unwilling to take.

Bush's original SAFETEA 2003 bill, introduced in May 2003, concentrated on striking a balance between conservative pressure to avoid spending and public pressure to create jobs through infrastructure construction. This proposal eliminated most discretionary highway-grant programs to reduce the possibility that states and localities would match projects to available pots of federal

money rather than prioritize based on transportation needs. Bush's bill proposed spending \$247 billion over six years, and he threatened to veto any bill that went much higher.

Despite TEA-21's expiration in September 2003, the Senate Environment and Public Works Committee did not have a preliminary version of the bill ready for markup until November. In February 2004, the Senate passed its SAFETEA bill, allocating \$318 billion; in April, the House of Representatives passed a TEA-LU version for \$275 billion.

However, the conference committee hit gridlock trying to negotiate a compromise. By September, the House introduced another six-month TEA-21 extension, signaling that no new bill would emerge until after the 2004 election. After starting over in 2005, the final conference's work was to find a middle-ground number between the House's \$284 billion bill, favored by the White House, and the Senate's \$295 billion bill. The president removed his veto threat, mainly because changes to the tax treatment of ethanol fuel meant the HTF expected \$18.9 billion in additional revenue.

SAFETEA-LU's final negotiated price tag of \$286.5 billion made it look like Congress had given in to the president's demands much more than the actual spending expectations associated with it suggest. The final bill actually authorized \$295 billion in spending, but ordered \$8.5 billion of that rescinded for fiscal year 2009, a provision that at the time was thought likely to be reversed by a future Congress. The funds were spent in 2009.

The final total funding levels represented a 30 percent increase over TEA-21 levels, and the legislation's high levels of earmarking became an issue in the 2006 Congressional elections. In its final form, SAFETEA-LU included 6,371 earmarked demonstration projects, totaling \$14.8 billion over five years. This represented a threefold increase over TEA-21. Notably, the "Bridge to Nowhere," one such project in Alaska, became a symbolic term for such pet spending projects in the political battles that followed.

Core Programs

SAFETEA-LU kept the five major Federal Aid Highway Program categories associated with ISTEA and subsequently reauthorized through TEA-21. These were the National Highway System (NHS), Interstate Maintenance (IM) Program, the Surface

Transportation Program (STP), Congestion Mitigation and Air Quality (CMAQ), and Bridge Replacement and Rehabilitation (BRR). It added a new core program, the Highway Safety Improvement Program (HSIP); previously, 10 percent of the STP funds were earmarked for safety programs.

Funding for these six programs represented about 60 percent of the bill total, with NHS and STP being the largest. SAFETEA-LU retained the provisions in TEA-21 that allowed states to shift funds among the formula-driven highway programs, and between highway and transit projects. In addition, an Equity Bonus, introduced as a distributional mechanism for ensuring state returns on funds contributed to the HTF and growth from existing funding, joined the core provisions of the legislation.

The NHS, with \$30.5 billion funding for 2005 to 2009, represented funding for major highway, interstate, and principal arterial roads projects. It retained TEA-21's formula of distributing funds based on non-interstate lane miles, vehicle miles traveled, diesel fuel, and population. The IM program, designated exclusively for maintenance on interstate highways, received \$25.2 billion in funding.

The STP, authorizing \$32.5 billion in flexible funds that could be used for public transportation capital projects or highway infrastructure, continued the 10 percent set-aside for transportation enhancement projects but no longer required 10 percent be spent on safety improvements. The CMAQ program, receiving \$8.6 billion, designated funds for any transportation project that could help meet Clean Air Act requirements, and the BRR program's \$21.6 billion could be used for replacement or rehabilitation of bridges on public roads.

Safety Programs

The new HSIP designated \$5.1 billion from 2006 to 2009 for projects meant to reduce traffic fatalities and serious injuries on all public roads. After setting aside \$220 million for the Railroad-Highway Crossing program, funds were distributed according to the number of miles of federal aid highways, the vehicle miles traveled on them, and the number of fatalities occurring on them.

In addition to this new program, SAFETEA-LU introduced several other safety measures. The Safe Routes to School program was intended to fund both infrastructure and behavioral programs that encouraged primary school children to walk or

bicycle to school. The Work Zone Safety program combined a grant program for worker safety training, and new requirements for temporary traffic-control devices and high-visibility clothing in work zones. Other provisions addressed issues such as improving sign markings, and bicycle and pedestrian safety.

Distribution and Equity Bonus

SAFETEA-LU's Equity Bonus program replaced TEA-21's Minimum Guarantee program. It was designed to ensure each state received a minimum rate of return on its contributions to the Highway Account of the HTE. The rate was raised in steps from TEA-21's minimum 90.5 percent rate in 2005 and 2006, to 91.5 percent in 2007, and 92.5 percent in 2008 and 2009.

With \$40.9 billion set aside for it from 2005 to 2009, the Equity Bonus became the single biggest program in the bill. In addition to the minimum return ratio from the HTE, the Equity Bonus Program also guaranteed that states would receive a minimum increase relative to their TEA-21 funding levels.

Planning Process Changes

SAFETEA-LU's changes to the metropolitan and statewide transportation planning process included elements meant to streamline the complexities that slowed projects and to incorporate new planning requirements. Among streamlining measures was lowering the updating frequency from every two years to every four years for metropolitan areas' Transportation Improvement Plans (TIPs) and Statewide Transportation Improvement Plans (STIPs); a similar schedule modification was made for recertifications of metropolitan planning organizations.

The act also established provisions for cooperative planning for projects spanning state lines. Safety and security were split into separate items for consideration in both statewide and metropolitan processes, in alignment with the administration's focus on antiterrorism efforts.

The biggest changes were in the environmental review process for transportation projects. SAFETEA-LU created a new category of "participating agencies" to broaden the planning process to formally include more state, local, and tribal agencies. It also instituted a requirement that the U.S. Department of

Transportation (DOT) inform Congress of any environmental issue that cannot be resolved in 30 days and set a 180-day statute of limitations for lawsuits challenging federal agency approvals.

SAFETEA-LU also provided greater flexibility in allowing exemptions to Section 4(f), which prohibits transportation projects on publicly owned lands, recreation areas, wildlife and waterfowl refuges, or historic sites unless there is no feasible alternative and all possible mitigation is used. Under SAFETEA-LU, compliance with 4(f) could be achieved through the determination that a project would have no adverse effects on an area and state officials with jurisdiction over the property concur with this determination.

Further, SAFETEA-LU exempted the interstate system from being treated as a historic site under Section 4(f). In addition, a pilot program allowed five states (Alaska, Ohio, Oklahoma, Texas, and California) to assume all DOT environmental compliance responsibilities for highway projects under the National Environmental Policy Act (NEPA) and other environmental legislation.

Tolling

SAFETEA-LU created two new programs to offer states more flexibility to create pilot tolling programs to finance interstate highway construction and reconstruction, and continued tolling-related programs created under TEA-21. The new Interstate System Construction Toll Pilot Program allowed up to three demonstration projects nationwide to collect tolls to finance interstate highway construction.

The Express Lanes Demonstration Program was created to allow up to 15 demonstration projects using tolling to manage congestion. SAFETEA-LU also left unchanged the Interstate System Reconstruction and Rehabilitation Toll Pilot Program and the Value Pricing Pilot Program from TEA-21, allowing up to three tolling projects to fund interstate reconstruction that would otherwise be unaffordable, and allowing up to 15 tolling projects in nonattainment areas to reduce congestion and air pollution, respectively.

Public-Private Partnership Funding Options

SAFETEA-LU included several provisions to encourage private-sector involvement in transportation infrastructure projects. It expanded the

scope of existing Private Activity Bonds (PABs) by adding highway facilities and surface-freight facilities to the projects eligible for these bonds, which give the same tax breaks as bonds issued by government bodies. The act also expanded the State Infrastructure Bank (SIB) program, allowing all states to establish infrastructure revolving funds to make loans or enhance credit for transportation projects.

New Technologies and Studies

SAFETEA-LU authorized \$2.3 billion for research (which was less than under TEA-21), and the funds were directed entirely to designated projects and studies. The National Surface Transportation Policy and Revenue Study Commission studied the current conditions and future needs of the surface transportation system.

The Road User Fees Study authorized a long-term field test by the University of Iowa's Public Policy Center to assess the implementation of a vehicle-miles-traveled fee. Finally, the National Surface Transportation Infrastructure Financing Commission was formed to develop policy recommendations to help the HTF achieve sufficient revenues to meet future needs. The commission's report in February 2009 recommended a 10-cent-per-gallon increase in federal fuel tax, and a 15-cent-per-gallon increase in the diesel fuel tax to keep the HTF from near-term insolvency.

Among demonstration projects, the Highways for LIFE Pilot Program targeted fostering the use of new technologies and more efficient highway building. A maximum of 15 projects could receive this incentive funding per year, but, ideally, each state would receive at least one project by 2009. Through this program, the DOT would help states demonstrate and promote state-of-the-art technologies and performance standards for the highway construction process for improved safety, faster construction, and reduced construction-related traffic congestion.

Continuation

SAFETEA-LU was set to expire on September 30, 2009. Despite warnings from the National Transportation Infrastructure Commission that the HTF was nearing insolvency, the President Barack Obama administration recommended reauthorizing SAFETEA-LU for 18 months at its original expiration date in September 2009 to provide funding stability while Congress dealt with other complex

agenda items such as health care. Instead, Congress passed a total of 10 shorter-term extensions until the signing of the Moving Ahead for Progress in the 21st Century (MAP-21) Act in July 2012. Thus, SAFETEA-LU largely defined the shape of federal involvement in American transportation for seven and a half years, well beyond its original scope.

Scenic Roads and Parkways

The evolution of the automobile has transformed roads from the science of strictly utilitarian transportation and economic necessities to the art of aesthetic assets. The federal government and local and state governments have cooperated in creating and maintaining scenic roads and parkways from the 1930s to the present.

Westchester County Parkway in New York and the Mount Vernon Memorial Highway in Virginia introduced an era of parkway and scenic road creation. In 1866 in New York City, Frederick Law Olmsted and Calvert Vaux had ideas about roads.

Originators of Brooklyn's Eastern Parkway in 1866, they felt that parkways were meant to restrict instead of encourage commerce. They believed parkways should be roads for pedestrians, bicyclists, equestrians, and carriages. Completed between 1870 and 1874, the Brooklyn Eastern Parkway was the nucleus of a plan for an interconnected park and parkway system in the New York area. The Olmsted and Vaux idea of bringing the countryside into the city influenced building major parks and parkways in cities across America.

Parkways Doubling as Freeways?

During the early 20th century, state and local governments expanded the Olmsted and Vaux definition of parkway to include landscaped limited-access highways designed for automobiles.

In its early days, the Vanderbilt Motor Parkway provided scenic routes without commercial vehicles or pedestrian traffic. Westchester County, New York, built four pioneering parkways between 1913 and 1930 and named them the Bronx River, Hutchinson River, Saw Mill River, and Cross County Parkways. The parkways were not built to establish the quickest and most direct route between origin and destination, but rather they were designed for moderate driving speeds so that motorists could enjoy the scenery.

Economic necessity, especially during the Great Depression, transformed the function of some parkways from beauty to business. The popularity of these parkways expanded the boundaries of New York City and led to its economic development. The building of the Arroyo Seco Parkway, the first part of the Southern California freeway system, during the Depression provided jobs for many people. When it opened in 1940, the Arroyo Seco Parkway reduced travel time between Los Angeles and Pasadena from 27 to 12 minutes. After functioning as the Pasadena Freeway and part of state Route 110 for decades, it was restored in 2010 and regained its original name.

In 1889, the U.S. Congress authorized a survey for the route of the Mount Vernon Memorial Parkway and passed enabling legislation for the parkway in 1928. In 1929, it renamed the project the George Washington Memorial Parkway. The parkway links George Washington's home at Mount Vernon, Virginia, with Washington, D.C., at the Arlington Memorial Bridge. Frederick Law Olmsted, Jr.,

Charles W. Moore II, and Gilmore D. Clarke helped create these first federal parkways. They borrowed some design features from the parkways in Westchester County, New York, and incorporated several ideas of their own and new technologies in road geometrics, bridges, pavement design, and construction that served as models for future highways and parkways. The National Park Service began administering the George Washington Memorial Parkway in 1933.

The New Deal Parkways

As part of the 1930s New Deal construction projects, the federal government built national parkways designed for recreational driving and earmarked to commemorate historic trails and routes. These parkways featured four lanes with lower speed limits. The National Park Service maintains these parkways, which include the Blue Ridge Parkway in the Appalachian Mountains of North Carolina and Virginia, the Skyline Drive in Virginia, and the Natchez Trace Parkway in Mississippi, Alabama, and Tennessee. The Colonial Parkway in eastern Virginia's Historic Triangle, the George Washington Memorial Parkway, and the Clara Barton Parkway that run along the Potomac River near Washington, D.C., were also built during the New Deal.

The Natchez Trace began as a buffalo and Native American trail and continued as a walking and riding trail for European traders and pioneers. The National Park Service Act of May 18, 1938, created the Natchez Trace Parkway as a National Park Service unit extending 444 miles from Natchez, Mississippi to Nashville, Tennessee, which preserves sections of the original trail. In 2009, the Natchez Trace Parkway had a total of about 5.9 million visitors enjoying scenic drives, hiking, biking, horseback riding, and camping. The sequestration provision of the Budget Control Act of 2011 required that the Natchez Trace Parkway budget be cut by 5 percent.

It took government agencies and private contractors over 52 years to complete the Blue Ridge Parkway, with the last stretch around Grandfather Mountain opening in 1987. The Blue Ridge Parkway grew into an economic necessity for the rural towns and villages along its route. In 2012, it drew an estimated 15.2 million recreational visitors to the area. The sequestration provision of the Budget Control Act of 2011 cut federal funding to national parks

and parkways and will adversely affect the tourist economy that is vital to the region.

Scenic Roads

With a few exceptions, state governments and the federal government did not formulate or adopt any organized plan of action for scenic roads in the first decades of the 20th century; instead, individual states and regions developed their own roads. Many were built sporadically for economic and practical reasons.

As early as 1913, Oregon authorized its first state highway commission to build a state highway system that included the Columbia River Highway in the Columbia Gorge that would preserve and compliment the area's beauty. Later highway commissions focused on protecting the environment as well as providing maximum recreation amenities for tourists. Oregon has designated 25 historic and scenic highway and bridge routes.

Vermont also instructed its State Highway Board to lay out a scenic route snaking through the central portion of the state from Massachusetts to the Canadian border; this later became Route 100. In the 1960s the Vermont state legislature addressed the problem of preserving scenic values along the state's highways.

States like Montana structured highways around their unique terrain and natural assets. In August 1872, Civil War General Philip Sheridan and 120 of his men crossed Montana's Beartooth Mountains returning from inspecting Yellowstone. Instead of detouring down the Clarks Fork River to Billings, General Sheridan followed the suggested route of an old hunter named Greer. When the Beartooth Highway opened in 1936, it followed General Sheridan's route over the pass.

When President Herbert Hoover signed the National Park Approaches Act in January 1931, the Red Lodge–Cooke City route of the Beartooth Road was the first park road to receive funding. The Beartooth Highway is a section of U.S. Highway 212 between Red Lodge, Montana, and Cooke City, Montana, that consists of a series of steep zigzags along the Montana–Wyoming border to 10,947-foot-high Beartooth Pass. It connects to the Chief Joseph Scenic Byway to Cooke City, forming the northeast gateway to Yellowstone National Park. Gateway communities scattered along the route depend on the highway for their economic

survival. The Beartooth highway officially opened on June 14, 1936.

The Great River Road

The Great River Road is an example of federal, state, and local governments cooperating over long distances to provide economic and aesthetic benefits to a large region of the country. Running along the Mississippi River from Minnesota to the Gulf of Mexico, the Great River Road is a 3,000-mile network of federal, state, and county roads that criss-cross the Mississippi River and encompass woodlands, river towns, farm lands, and villages.

The Mississippi River Parkway Commission (MRPC), comprised of members appointed by the governors of the 10 states along the Mississippi River, first proposed the idea of an extensive river road to federal officials in 1938. After World War II, Congress granted funds for a feasibility study for the road, and in 1954, it approved the road. Since then, the Great River Road has continually been developed using state funds and federal aid. In 1964, Congress expanded the northern boundary of the Great River Road from Lake Itasca in Minnesota to the Canadian border, permitting the provinces of Ontario and Manitoba to connect the 5,000-mile Trans-Canada Highway to the Great River Road.

National Scenic Road Programs

Despite impressive local and region scenic highways, a coordinated national scenic highway program did not appear until the 1960s. In 1962, President John F. Kennedy established the Recreation Advisory Council that included Secretary of the Interior Stewart Udall; Secretary of Agriculture Orville Freeman; Secretary of Defense Robert McNamara; Secretary of Commerce Luther Hodges; Secretary of Health, Education, and Welfare Anthony J. Celebrezze; and Administrator of Housing and Home Finance Agency Robert C. Weaver. The mission of the Recreation Advisory Council was to pinpoint recreational opportunities in America, and in its 1964 report the council recommended developing a national program of scenic roads and parkways.

The Recreation Advisory Council said that driving for pleasure was one of America's most popular outdoor recreational pursuits, and the number of families driving for pleasure would make an economic impact on tourism and sightseeing on scenic highways and parkways. The completed study, "A

The Linn Cove Viaduct around Grandfather Mountain on the Blue Ridge Parkway was the last stretch of the parkway to be completed, opening in 1987. It is a precast concrete segmental viaduct and the most complex structure of its type to be built in the United States at that time. It took 52 years to complete the entire Blue Ridge Parkway, which drew an estimated 15.2 million visitors in 2012.

Proposed Program for Scenic Roads and Parkways,” was published in June 1966; it recommended a scenic highway program and laid out its financing

On May 24–25, 1965, President Lyndon B. Johnson hosted a White House Conference on Natural Beauty for America to discuss environmental issues, including scenic roads. Congress passed the Highway Beautification Act of 1965, which provided for the scenic development and road beautification of the federal aid highway system.

Americans Outdoors and Scenic Roads

In 1985, President Ronald W. Reagan issued Executive Order 12503, establishing the Commission on Americans Outdoors. Chaired by Lamar Alexander, the commission published its findings in 1987, updating the Outdoor Recreation Resources Review Commission reports of the 1960s. The 1987 report included three recommendations for scenic

roads. The commission recommended that local and state governments create a network of scenic byways and act to protect them, and it suggested that Congress should establish an incentive program of matching grants from the Highway Trust Fund to encourage scenic byways development. It recommended private sector and government partnerships to provide information on scenic byways.

The Intermodal Surface Transportation Efficiency Act of 1991 established the National Scenic Byways Program, and the Transportation Equity Act for the 21st Century (TEA-21) reauthorized it in 1998. Under the program, the U.S. secretary of transportation recognizes certain roads as National Scenic Byways or All-American Roads based on archaeological, natural, cultural, historic, recreational, and scenic standards. There are 150 byways in 46 states. Arroyo Seco Parkway, Blue Ridge Parkway, Beartooth Scenic Byway, George

Washington Memorial Parkway, the Great River Road, and the Natchez Trace Parkway are all National Scenic Byways.

School Bus Safety

Carrying over 25 million U.S. children daily, school buses represent a major source of transportation. With nearly 500,000 school buses traveling nearly 5 billion miles per year, the scope of America's school transportation program is both enormous and diverse.

Because of the long tradition of local control over public schools in the United States, a variety of local authorities administer school busing. This local control is tempered, however, by state and federal regulations designed to assure the safety of all riders. School bus safety involves consideration of factors involving construction, operation, regulation, and maintenance of the fleet and its drivers to assure the well-being of youthful riders. As with most considerations of this type, costs and benefits are carefully weighed so that school bus transportation balances safety and efficiency.

School buses remain the safest mode of transportation for children going between home and

school. Buses are also an effective means of reducing traffic on roads and near schools, which in turn protects pedestrians. While many school buses are owned and operated by school districts, others are controlled by third-party contractors who run them on behalf of schools and other organizations. Because of the importance accorded to children's well-being, school bus safety continues to be of concern to many facets of society.

Background

As public education became more common during the 19th century, transportation of children to schools became an issue of consideration. Children in rural districts often lived distances that were judged too far from their schoolhouse to be practical to walk. As early as the 1820s, horse-drawn buses transported children in England to school in a manner that was relatively safe, convenient, and efficient.

By the mid-1880s, Richmond, Indiana-based Wayne Works was manufacturing horse-drawn school carriages, which featured entry and egress through the rear of the vehicle, done in part so that children loading or unloading from the bus would not startle the horses. Once motorized school buses began being manufactured, this rear exit was maintained, as was perimeter bench seating within the vehicles that was attached to the walls. The first school buses were developed solely for local need, and varied greatly depending upon the place of manufacture.

While early motorized school buses featured roll-up canvas curtains as a means of covering windows in the passenger compartments, by the early 1920s Wayne Works began to offer glass windows in most of its vehicles. Gillig Bros., a San Francisco, California-based bus manufacturer, had introduced glass windows earlier, along with the "California top" roof, which featured a slightly curved metal top to the bus, with windows separated by regularly placed pillars that permitted each window to be opened using a latching mechanism. During the 1930s, Wayne Works and Crown Coach Corporation of Los Angeles, California, began offering all-steel-body school buses. Crown Coach's "Supercoach" was the highest capacity school bus of its era, seating 76 passengers.

During the 1930s, school buses began to be viewed as a distinct product, rather than an

adaptation of an existing product to be used to carry children. Based upon wagon manufacturing principles, school buses thus tended to be largely custom built, which decreased profitability for manufacturers, increased costs for school districts, and resulted in a hodgepodge of practices and customs. As standardization was seen as a benefit to profitability, decreased cost, and increased safety, certain features began to be found in all buses. To this end, innovations such as Gillig's steel-reinforced "California top" became the industry standard. As the automotive industry at large embraced all-metal-body construction of vehicles, school buses, which until this time had used a great deal of wood in their manufacture, also embraced this change.

In an effort to improve school bus safety, Professor Frank W. Cyr of Teachers College at Columbia University organized a national conference that met in New York City in 1939. Cyr, an expert in rural education, was keenly interested in school bus safety but realized that manufacturers also had concerns regarding the cost and construction of the vehicles. At this conference, Cyr was able to begin discussion that led to an agreed-upon set of industry-wide standards for school buses, a step that changed their design and production for the better.

Cyr, later referred to as the "father of the yellow school bus," was able to get transportation officials, school board members, bus body and chassis companies, paint manufacturers, and other interested parties to attend this conference. As a result of Cyr's efforts, a set of 44 standards for school bus construction were adopted by all manufacturers. These 44 standards led to consistent interior dimensions, seating configurations, and other features that permitted new consistency in industrial processes for body manufacturers. The adaptation of these standards led to decreased complexity in the manufacture of school buses, which also reduced the unit price for purchasers.

Ways of increasing school bus safety were also considered by conference attendees. After reflection, attendees determined that yellow was the easiest color to see at both dawn and dusk and, as a result, adopted what is now known as National School Bus Glossy Yellow as the standardized school bus color. Although this choice was never officially adopted by the federal government, it has become the de facto choice for school buses both

in the United States and globally. The success of the Teachers College conference led to continued efforts to improve the safety of school buses.

Evolving Safety Concerns

The decades immediately following World War II saw a baby boom that resulted in rapid growth in the school-aged population in the United States, especially in urban and suburban school districts. As a national shortage of building materials precluded immediate school construction to meet this need, school districts were forced to rely upon increased use of school buses instead.

For the first time, school buses began to evolve from what had primarily been a means of transporting rural children to school into a means of more fully utilizing the capacity of existing facilities. Conventional school buses, that is, those built on a truck chassis and sometimes referred to as Type C school buses, began to see increased competition from two variants. The first variant, transit-style school buses, offered increased capabilities such as greater seating capacity and better handling over conventional school buses. The second variant, small school buses, proved better able to handle routes that were inappropriate for conventional buses or that were intended for younger students or those with special needs.

By the 1950s, eight major school bus body manufacturers controlled production in the United States: Blue Bird Body Company; Carpenter Body Works; Crown Coach Corporation; Gillig Corporation; Superior Coach Company; Thomas Built Buses, Inc.; Wayne Corporation; and Ward Body Works. These manufacturers produced bodies for chassis made by three suppliers: Ford Motor Company, General Motors Corporation, and International Harvester Company.

The distinctive flat front-end design of the transit-style school bus, also known as Type D buses, makes them more similar to buses used in mass transit. As school enrollments boomed, transit-style school buses grew in popularity, especially on the West Coast, because this style had a larger capacity than conventional school buses. Maintenance and operating costs for transit-style buses were lower, as the increased capacity required a smaller fleet of buses, thus requiring fewer maintenance checks, drivers, and other associated costs. Small school buses, sometimes referred to as Type B buses,

proved useful for special school programs, such as those serving the gifted and talented or those associated with music and the arts. Small school buses are often equipped with special devices to assist people with disabilities, such as automated lifts.

As the federal government became more concerned with vehicle safety overall, this interest extended to school buses as well. Beginning in 1977, the Federal Motor Vehicle Safety Standards for School Buses were initiated. These have played a role in changing the design and construction of school buses, alterations made in an effort to make these vehicles safer and more reliable for the children they serve. In all, over 35 federal motor vehicle safety standards apply to school buses, with several written specifically for those vehicles. As U.S. congressional concern has ebbed and flowed regarding school bus safety, these standards have been revised, rewritten, and expanded.

Safety Modifications

Certain safety modifications that have been mandated for school buses have affected all motor vehicles and have been relatively simple to implement. Others have been specifically designed for school bus manufacturers and have proven very costly. Still other proposals have occasionally generated popular support but have proven difficult or impossible to achieve.

Beginning in the 1970s, for example, school buses, and indeed all motor vehicles, were required to have rearview mirrors installed in an effort to reduce the number of injuries that occur when a driver does not possess a clear and unobstructed view to the rear. Similarly, electronic stability control systems have been mandated on all multipurpose vehicles weighing in excess of 10,000 pounds, including school buses, in an effort to reduce the risk of roll-over crashes and the potential deaths or serious injuries they may cause. Because these alterations were required on all vehicles, an economy of scale exists that makes the cost of such modifications to the design process reasonable and affordable.

Federal standards have also required that all body panel joints that comprise school bus bodies be strengthened, reducing the chance of structural collapse of school bus bodies during crashes, thereby reducing deaths and injuries resulting from these crashes. Additionally, all school buses were required to have higher, well-padded seats installed,

which provided increased protection to passengers in the event of a crash. Although this standard applies only to school buses, the universality of its nature levels the competitive playing field insofar that every bus manufacturer and operator must bear the same expense.

For decades, certain groups have advocated for safety belts on school buses. Despite demands for seat belts on school buses from some quarters, in 1977 the federal government instead decided to strengthen structural requirements for the vehicles in conjunction with better passive restraint requirements. These changes exempted school buses that weigh in excess of 10,000 pounds from having to install seat belts.

Opponents of seat belts on school buses assert that their superior construction and safety features make them safer than automobiles, making the passenger restraint devices found on the smaller vehicles unnecessary. Data from the National Highway Traffic Safety Administration indicates that a child is 50 times more likely to be killed on the way to school if traveling in an automobile driven by themselves or their friends than if they take a school bus.

Several states now require seat belts on certain school buses. These states include California, Florida, Louisiana, New Jersey, New York, and Texas. Beginning in 2011, the federal government has begun requiring the passenger restraints on van-based (Type A) school buses. Seat belts potentially reduce the number of children that can be served by a single school bus, especially in states such as New Jersey where every child is required by state law to wear a seat belt (in other jurisdictions, this is the choice of the school district) or in states such as California that require three-point (shoulder) seat restraints. Either of these options could require the purchase of more vehicles, as the existing fleets would be unable to serve the same number of children while also complying with the new seat belt requirements.

Traffic Laws and Safety Devices

Since the 1939 Teachers College conference on school bus safety, most school buses have been painted the color known as National School Bus Glossy Yellow. Once school buses became instantly recognizable with their distinctive color scheme, it became easier for states to promulgate, and enforce, traffic laws related to school buses.

For example, by the mid-1940s, the majority of states had passed traffic laws that required other vehicles to stop whenever a school bus was loading or unloading children.

This prohibition was popular because many children do not fully comprehend the hazards and potential consequences presented by traffic, and the size of the large yellow bus often limits the sight lines for both children and adults. In all 50 states and the District of Columbia, other traffic must stop when a school bus is loading or unloading, although the distance kept by other vehicles varies depending upon jurisdiction.

As the understanding of the potential threats to children have increased, and as technology has advanced, a variety of safety devices have also been installed on school buses to better protect passengers. Warning lights first began being used on school buses in 1946 in Virginia. At that time, Virginia buses used a series of four red lights, two each to the front and rear of the bus, to indicate that boarding was taking place. Automated either by a mechanical switch attached to the door control or via a pressure-sensitive switch connected to a paddle-operated stop sign located to the left of the driver's seat, the warning lights alternated to warn other vehicles of the possible presence of young pedestrians.

As time has evolved, many states now have increased the number of warning lights needed to eight, four in the front and four in the back. While some states require the use of a combination of both amber and red lights, other jurisdictions such as Wisconsin mandate that all lights used be red.

Beginning in the early 1950s, some states began permitting the use of a mechanical stop sign that would swing out from the left side of a bus when a stop was in progress. The stop sign was intended to warn passing traffic that a stop was in progress. Initially it was a rectangle with the word "Stop" printed on it, but the U.S. National Highway Traffic Safety Administration now has established a standard for all such stop arms. The mechanical sign now must be a double-faced regulation red stop sign, octagonal in shape, and at least 17.7 inches across, using a white border and uppercase letters. The mechanical sign must be equipped with flashing red lights, use reflective paint, or both. Some mechanical signs use light-emitting diodes (LEDs) to further focus the attention of drivers of other vehicles.

All school buses have an emergency exit door located in the rear of the bus, a feature that dates to the horse-drawn wagons that predate modern motorized vehicles. These rear emergency exits, which are window exits in the event of a rear-engine bus, are augmented by additional escape modes. These may include roof hatches, window exits, or side emergency exit doors, or a combination thereof. These exits are activated by a release latch, which simultaneously activates an alarm at the front of the bus. The number of exits required on a given bus varies, depending upon its capacity and the governing jurisdiction's requirements.

Federal motor vehicle safety standards also require the use on school buses of retroreflective conspicuity tape along the sides and rear of buses to indicate their height, width, and length. The use of such retroreflective conspicuity tape assists other drivers, making it easier for them to see the size of the bus in darkness or inclement weather—the combination of the tape and the drivers' own headlights allows them to more correctly perceive the vehicle's size and position. All emergency exits must also be so marked, so that first responders and other emergency personnel can quickly identify these in the darkness.

Additional Safety Standards

Individual jurisdictions have used advancing technology to provide additional features that improve the safety of children on school buses. For example, Illinois and many school districts in other states require strobe lights to be used on the roofs of buses. As the cost of video technology has decreased, many school districts and contractors now require video cameras to be installed inside school buses. Although initially installed primarily to monitor and record passengers' behavior, video technology has also been useful in detecting inappropriate or illegal behavior on the part of school bus drivers or other personnel.

Despite all of these safety efforts, nearly 66 percent of students killed outside a school bus are killed not by another vehicle but by the bus that they regularly ride. In an effort to improve safety, comprehensive mirror systems have been developed in an effort to reduce bus drivers' blind zones. Windshields on Type C and Type D buses have been enlarged in an effort to remove obstacles from a driver's line of sight.

As video technology advances, this has greatly assisted in improving bus drivers' awareness of children around their vehicles. Increased emphasis has also been placed upon improved education that assists children in recognizing dangerous situations and utilizing the appropriate level of care to avoid tragic injuries or death.

kindergarten students may be driven to school by their parents or a car pool, especially in districts where the kindergarten is not integrated with the elementary school.) The major exceptions are urban school districts where children take ordinary public transportation or live close enough to walk. In exurban and rural districts, walking may be permitted (or required) of students who live within a given radius of their school, and driving may be required of students who live outside a second radius, a factor that has to be considered when building new housing developments or residential streets.

Originally, students were expected to walk to school, and buses were introduced in rural areas for the sake of students on far-flung farms and ranches. The earliest buses were horse-drawn carriages called "school trucks," and were equipped with a rear door for entry so that boarding students would not upset the horses (intentionally or otherwise). The first buses with engines retained this rear door, which today is used as an emergency exit. The modern school bus originates in the 1930s and 1940s, when "school bus yellow" was introduced as a standardized bus color. Believed to be the easiest color to see in dark or winter twilight conditions, school bus yellow is officially called National School Bus Glossy Yellow in the United States. Though not mandated federally, and a small share of school districts use other colors, most districts and manufacturers have used National School Bus Glossy Yellow for decades.

Around the same time that school bus yellow was introduced, most of the country adopted—often as part of a new wave of traffic laws, reflecting the increasing role driving played in American life—new laws requiring traffic to stop while children are boarding or disembarking from a school bus. Many also require drivers to maintain a greater than normal distance from school buses in front of them, for a number of reasons: it keeps the car out of the bus driver's blind zones, it reduces the odds of a rear-end collision, and it provides additional braking time in the unlikely event that a child manages to open the rear emergency exit.

The three most common types of school buses are deployed for varying purposes. The conventional school bus design, Type C, uses a truck chassis, resembling an elongated truck cab with modified doors and windows. This has remained the most popular school bus type in the country for

School Buses

In the United States, school buses are the default form of transportation for public school students in most districts. (At least for grades one through 12; because of their young age, in many places

default school transportation. In some districts, the more recent transit-style or Type D of school bus, which has a flat front like a motorcoach or public transit bus, has become more popular, in particular on the West Coast where the first popular model thereof was developed, in the 1950s. Type D buses have a larger passenger capacity than the conventional bus and so are more likely to be deployed in densely populated districts or those with rapidly expanding populations. Smaller school buses based on the chassis of a van (Type A buses) or step van (Type B buses, rarely manufactured today but still in use in some fleets) are often used for specialized low-ridership purposes like the transportation of disabled students, magnet school routes, or special occasion travel such as field trips.

Safety Standards

The Federal Motor Vehicle Safety Standards for School Buses were established in 1977, and along with the standards established by other laws, a total of 37 federal motor vehicle safety standards apply to school buses (though not all 37 are relevant to every model of school bus). For instance, in 1991 the extendable stop arm was mandated as a pedestrian safety device in order to notify approaching traffic of their requirement to stop until schoolchildren (or other disembarking pedestrians) have left the street. It has been amended several times, most recently in 1998, when strobe lights and LED lighting was permitted. Other standards mandate electronic stability control, standards for mirror placement and design, crash protection, emergency exits, seat belt assemblies, durable and well-padded seats, reinforced body panel joints in order to reduce fatalities in the event of structural collapse, and rollover protection. According to a 2002 report by the National Highway Traffic Safety Administration, students are significantly safer in schoolbuses than driving to school by car—eight times safer.

Fuel

Recent debates about school bus policy have often centered around fuel consumption, both for economic reasons—oil price shocks wreaked havoc on the budgets of school districts in the late 2000s, for instance, as they had done several times in the 1970s and 1990s—and for environmental reasons. Environmental concerns over the exhaust produced by school buses are not limited to the effects thereof

Yellow school buses in a parking lot near Coney Island in Brooklyn, New York, in 2006. The rear door exits seen here evolved from the rear exits of early horse-drawn "school trucks."

on climate change; many parents and others also worry about the health effects of the exhaust on students waiting near idling buses to leave school.

Many fleets adopted diesel engines in the 1980s, during a resurgence in the popularity of diesel fuel as an alternative to conventional gasoline. They have since become the predominant engine type, making possible conversion of school bus fleets to biodiesel consumption. While explored in many school districts and pilot projects, biodiesel conversion has been popular primarily in affluent districts and districts awarded federal or private-sector grants. While school transportation was largely neglected in the first part of the federal economic stimulus package of 2009, later programs established with stimulus money did deal with converting school bus engines to biodiesel or compressed natural gas.

GPS

As GPS technology has become cheaper, many manufacturers have offered it as an optional feature in their buses. GPS is used not only for safety purposes but for fleet management, allowing a central

authority to keep track of where on the route each bus is, what delays are being experienced, and other factors. Though there are safety concerns about revealing location information in real-time, some districts allow parents to access it (in order to be sure they meet their child at the bus stop, for instance) or to receive proximity alerts on their phones. In the unfortunate event of a missing or abducted child, these systems also provide investigators with more granular information about the child's last known location.

School Transportation

School transportation is the transportation of students to and from school, especially the daily transportation of minor children. About 25 million American children depend on the school bus as their primary means of school transportation, though there are transportation issues faced by boarding schools (for which transportation is less than daily) and universities, where students reside on campus and need transportation across campus or from campus to various local destinations.

Such busing is nearly always zero-fare, and in many cases, bus drivers are familiar with the students on their route and no ID or pass is required.

School transportation includes bus transportation, which itself includes the use by schools of an existing bus transit service, as well as the maintenance and dispatch of a dedicated school bus fleet. Students also may arrive by foot or bicycle, be driven to school by car by parents or others, or drive themselves once they reach driving age.

Transportation policy needs to address the basic need of getting students to school, as well as how the school will handle the impact of unusual events on transportation, such as delayed openings or early closings due to weather; the transportation of students from the school to other destinations, such as on field trips; the transportation of students who remain on campus for after-school activities or because of after-school detention hours; the transportation of student athletes (and spectators) to away games; and the transportation of students to sanctioned events for student groups, such as debates or academic competitions.

A transportation policy must also encompass the handling of exceptions to whatever the transportation norm is for the school. In a school in which students are picked up at home and transported to school by bus, for instance, policy would address the handling of students who want to walk, bicycle, or drive to and from school instead; students who want to take the bus to a friend's home after school; the handling of traffic caused by parents picking up or dropping off children in lieu of using the bus; and the various legal and liability issues brought up by transportation policy and the responsibilities of the school to the minors in its care.

In North America, it is common for public schools to use fleets of dedicated school buses painted National School Bus Glossy Yellow, a paint color developed in 1939 specifically for this purpose. The color is designed to be easily noticed by drivers in their peripheral vision and rearview mirrors, and to stand out in traffic. It also makes the bus easily identifiable by young children. The visibility of school buses is important not only for safety purposes—because the bus makes frequent stops, it is important for drivers to be aware of its presence—but also because a number of traffic laws privilege the school bus and require certain behaviors of drivers.

In almost every state, for instance, drivers (regardless of lane or direction of traffic) must stop when a school bus is loading or unloading passengers. This shifts the burden of safety from the children to the drivers, essentially stopping traffic until children are either safely on the bus or have moved away from the street. Often a school bus will be equipped with a foldout double-faced stop sign (called a stop signal arm) reminding drivers of this, although the law is binding regardless. Other warning devices may include flashing lights.

Sometimes, depending on policy or the driver's own practice, the bus will remain stopped until disembarking children have left the bus stop. In particular, the bus often remains in place—forcing traffic to remain halted—until any children who need to do so have crossed the street. The usual exception to the school bus traffic priority law is on divided highways, where only traffic headed in the same direction as the bus is required to stop (New York is one of the few states without this exception). Because violations are common but difficult to prove, the beginning of a new school semester is often accompanied with increased traffic police presence in order to crack down on violators.

Transportation policy considers not only safety practices and the manner of bringing children to school but also the consequences of transportation policy choices in other spheres. School bus pollution is considerable, for instance, though it is much less than the same pollution that would be contributed by individual cars carrying the same number of students to school (even if that number were reduced through carpooling).

Nevertheless, school buses tend to remain in use longer than the average passenger car and are designed for durability and longevity so that their cost can be amortized by the school board or transit agency over a long period of time. For this reason, many of the school buses in use at any given time are considerably less fuel efficient and bigger contributors to greenhouse gas emissions than equivalent new models would be. There are a number of federal, state, local, and private-sector initiatives aimed at encouraging schools to convert their fleets to cleaner buses, either by phasing out older buses or by converting gasoline- or diesel-powered buses to those using biofuel, methanol, compressed natural gas, electric hybrids, or other alternatives.

Campaigns against childhood obesity and in favor of childhood physical fitness have often advocated active transportation, meaning transportation by foot or bicycle. Access to walking or bicycling has been frequently correlated to better fitness levels and higher daily levels of physical activity, and active transportation programs can increase that access. This is an area, though, where transportation policy is limited by other policies enacted by other entities.

The ability of a child to walk to school, or to walk safely in his or her neighborhood at all (or that of the school), is determined by the built environment: the man-made surroundings of the neighborhood, including the presence and upkeep of sidewalks, public parks, footpaths, and crosswalks, and the amount of traffic that must be negotiated. Childhood obesity is more prevalent in neighborhoods with poor walkability because of these factors, but those neighborhood factors also make walking to school a less practical solution.

Federal grant money is available to states that develop Safe Routes to School programs, which are designed to encourage children to walk or bicycle to school by developing and implementing projects to increase walkability and bicycle usage. In order to reduce concerns about unescorted minors walking to school, the “walking bus” and “bicycle train” concepts are sometimes used, each of them consisting of a group of walking or bicycling children (increasing in size as they follow a route taking them past other students' homes) led by adult chaperones.

Desegregation

School transportation also includes busing for the purposes of desegregation, a practice especially associated with the 1970s and 1980s, and somewhat less common now. Before the 1954 Supreme Court decision in *Brown v. Board of Education* made racial segregation unconstitutional, there were essentially two forms of segregation in the United States: segregation by explicit policy (de jure segregation), in which separate schools were maintained for students according to race, and de facto segregation, in which schools were primarily or exclusively white or black because of school district zoning and factors other than explicit policy.

In some cases, de facto segregation was created in order to bypass the court's ban on de jure

segregation. A school district could be created consisting of most of a city's predominantly black neighborhoods, for instance, essentially creating an all-black school without need for an explicit policy. In other cases, especially in the north, de facto segregation existed because of long-standing traditions of settlement and the tendency of neighborhoods to be racially homogenous (a tendency that in various eras had been reinforced by federal and state housing policies and the mortgage-lending policies of banks, as well as by the real estate industry).

However, de facto segregation was not spared for long, and in a lesser-known 1971 case, the Supreme Court recognized the federal government's power to use busing for desegregation. In such a practice, students are bused to schools to which the local district division would not otherwise assign them, in order to break conditions of de facto segregation.

Desegregation busing began in Boston when Massachusetts passed the first-in-the-nation Racial Imbalance Act, which tied state education funds to desegregation. The busing plan implemented in the Boston area was fiercely opposed in the Irish American neighborhoods of Charlestown, Dorchester, South Boston, and Roslindale and the Italian American North End. As implemented by Judge Arthur Garrity, Jr., Boston busing was not a matter of shifting a small number of students; Garrity ordered large numbers of students to be redistricted, in one case busing the entire junior class from a mostly white school to the predominantly black Roxbury High School. Protests were fierce, and many of Garrity's choices were questioned even by busing advocates. Boston busing eventually ended in 1988, at which point the Boston school district had shrunk to nearly half its previous size.

Boston had experienced the same phenomenon that was at work in much of the rest of the country and that was responsible for the decline of busing: white flight, as middle-class and lower-middle-class white families left the city centers for the suburbs. The schools they left behind became less predominantly white as a side effect, as nonwhite families filled in the empty spaces. In other cases, wealthy families increasingly sent their children to private schools where conditions of de facto segregation were common, but beyond the reach of federal policy.

Section 504 Regulations on Accessibility

The Rehabilitation Act of 1973 marked the first substantive legislation in the United States designed to ensure equal treatment and services for individuals with physical or cognitive disabilities. Its doctrine expressly prohibits discrimination on the basis of disability in federal government and federal contractor employment practices, in programs administered by federal agencies, and in any program receiving federal financial assistance. Public transportation operations fall under these categories, making them subject to compliance with the act's regulations.

The underlying principle of the act is that mass transit should not hamper the ability of people with disabilities to participate fully in society and actively engage in employment, educational, and cultural opportunities. As such, U.S. public transportation systems are required by law to provide accommodation that enables access to public transit by

individuals with disabilities. The transition toward greater access following the Rehabilitation Act in the 1970s was initially a rocky one, requiring additional regulations to clarify definitions and responsibilities. Over time, however, the broad social and economic benefits from greater access to public transportation for all individuals have become more evident.

Components and Definitions

When passed by Congress in 1973, the first three titles of the Rehabilitation Act provided for a wide range of vocational rehabilitation services, including research and training, and outlined federal responsibilities. The fourth title established the National Council on the Handicapped, which became an independent federal agency in 1984 known as the National Council on Disability, responsible for advising the president, Congress, and other U.S. federal agencies regarding programs, practices, and policies affecting individuals with disabilities.

The act's fifth title addressed miscellaneous provisions and included four key segments. Section 501 prohibited discrimination against the disabled by the federal government. Section 502 targeted reduction of mobility barriers for disabled individuals in public places. Section 503 prevented discrimination against the disabled by government contractors. Section 504 barred federally funded programs from discriminating against individuals with disabilities. The final two titles of the Rehabilitation Act, Titles 6 and 7, dealt with employment opportunities and independent-living services for the disabled.

The original definition of a disabled person in the Rehabilitation Act of 1973 included only individuals who had a physical or mental impairment resulting in a significant hindrance to employment, and who could reasonably be expected to gain employability advantage as a result of vocational rehabilitation services as provisioned under the first three titles of the act. However, in 1974, Congress amended the Rehabilitation Act under Section 504 to expand the definition of a disabled individual beyond the specific employment scope.

The broader definition identified a disabled person as someone who is regarded as having a physical or mental impairment that significantly limits one or more major life activities, which may include anything from seeing or walking to learning or breathing. Essentially, any limitation that debilitates

one's independent living or inclusion in U.S. society could be considered a disability under the expanded definition. The amendment was intended to ensure that federally funded programs are operated without discrimination against any disabled individual, not just those whose disability affects their employment status or experience.

Each federal agency has its own set of Section 504 regulations that apply to its own programs. Agencies that provide federal financial assistance to others also have Section 504 regulations pertaining to the entities that receive the federal aid. Requirements common to both categories of the regulations include providing reasonable accommodation for individuals with disabilities, ensuring program accessibility to those individuals, delivering effective communication to individuals who have hearing or vision impairments, and providing accessible facilities in new construction or modifications to existing sites and equipment. Each agency is responsible for enforcing its own regulations.

Impact on Transportation

As a result of Section 504 of the Rehabilitation Act of 1973, the Federal Transit Administration (FTA), which was then known as the Urban Mass Transportation Administration, issued regulations that required special efforts to be made in the planning of public mass transportation facilities to accommodate the needs of elderly and disabled individuals. The regulations also required that all new transit vehicles and facilities be accessible to the disabled.

More stringent regulations were published in 1979, mandating that all existing bus and rail systems that received federal funding be retrofitted to become fully accessible to disabled persons within a three- to 30-year time span, depending on the size and type of transit operation. For example, the 1979 regulations required that 50 percent of the buses in fixed-route service be modified to ensure accessibility and safety for wheelchair users within the first three years, while railcar retrofits, including bathrooms and sleeping compartments on long-haul trains, had up to five years to comply. Rail facility accommodations were given a 30-year window. Transit operations had to show steady progress toward achieving accessibility in order to be considered compliant.

Additional regulations adopted in 1986 established six service criteria that applied to urban mass

transit systems—with some exceptions applied to existing rail systems—for individuals with disabilities. First, anyone who is physically unable to use the public bus system must be treated as eligible for special accommodation. Second, the accommodating service must operate during the same days and hours as the general service. Third, the specialized service must operate in the same geographic area as the ones serving the general public. Fourth, passenger fares for carriage on both the specialized and public services must be comparable. Fifth, the specialized service must be provided within 24 hours of a specific request. Finally, restrictions or precedents for specialized service may not be imposed based on the reason for the travel itself. In other words, the purpose of the travel cannot serve as a basis for limitation or prioritization of service.

Transit authorities were allotted a one-year planning stage in which they were required to involve the disabled community and other interested parties from the public. They had up to six years after planning to phase in the new services and, again, were required to include disabled participants throughout the implementation process. To prevent undue financial burden on transit authorities, the regulations capped the amount of money transportation agencies were required to spend on the provision of specialized services to 3 percent of their annual operating expenditure. This limit was lifted in 1990 when the Americans with Disabilities Act (ADA) was adopted.

Rulemaking for the Section 504 regulations was one of the most complex and drawn-out processes in U.S. Department of Transportation history. It required balancing the concerns of the disabled community that needed sufficient access to public transportation with the concerns of transit authorities and local governments that wanted to avoid costly and time-intensive accommodation requirements.

The balancing act stimulated a fierce debate between those who felt that disabled individuals should have the right to be mainstreamed into society and those who believed that there were more cost-effective ways of providing transportation for that group using paratransit services. Paratransit is essentially on-demand, door-to-door services for individuals or small groups who are physically unable to use standard public transit systems.

The latter contention was based on the widespread opinion among transit professionals that

there were not enough new transit passengers to validate the expense of providing mainstream transit access for individuals with disabilities. However, the reality was that demand for paratransit services far exceeded the expectations of transit agencies, with eligible passengers using the specialized services more frequently and for more purposes than had been estimated by transit planners. Transportation agencies have been trying to manage regulatory requirements and higher demand for specialized services ever since, while contending with generally flat funding, diminished utilization, and declining service quality in conventional transit services.

Broad Economic Benefits

To promote compliance with Section 504 of the Rehabilitation Act and the subsequent ADA, the FTA points transit authorities to the economic benefits of providing transit access for individuals with disabilities. For example, there are direct economic benefits to the individual using the service and to those in his or her household because the individual is able to participate in employment and educational opportunities. Accessible transit for the disabled also imparts incremental benefits to other transit passengers who are not counted as having disabilities in that it strengthens and diversifies the workforce, reducing the burden on those who would otherwise carry the full fiscal load.

Additional economic benefits can be found in the costs saved by public and private businesses when their clients and customers have ready access to them via specialized transit services. Moreover, the increased participation in society among formerly isolated individuals and the regular use of specialized transit services produce overflow benefits to the general taxpayer by way of producing a more efficient economy.

Consider a dialysis patient, for example. When a transit provider offers mobility services that enable a dialysis patient to receive needed treatment, it eliminates the use of costly ambulance shuttle services that would otherwise be used in some cases. For patients whose medical travel is paid by publicly funded medical assistance programs, the savings to both health and human services agencies and taxpayers is potentially significant.

The U.S. Department of Transportation routinely measures the economic value of transit accessibility based on perceived benefits not only

for passengers with disabilities but also for local taxpayers and the public at large. The findings have suggested that the benefits from accessible transit services are substantial and far exceed the start-up and maintenance costs of most specialized transit services. More than favorable economics, however, accessible transit services provide disabled individuals with greater independence and improved quality of life.

Security, Transportation

The contemporary international scene is characterized by ever-increasing mobility of people, capital, and goods. Such mobility depends on an effective transportation system, one that is secure from disruption by international terrorism. Attempting to ensure that people can continue to avail themselves of various mobility options and that trade can continue to flow smoothly and economically has become an international priority.

Terrorist attacks have inflicted serious damage to transportation facilities in many countries. Airports and airlines have been attacked in Israel, Spain, India, South Korea, and Scotland, as have mass transit facilities in Spain, the United Kingdom, and Japan, often with devastating consequences in terms of human lives and economics.

The issue of how to improve security in transportation is greatly complicated by the growing economic and personal interconnectedness that characterizes the modern world, as technological changes in transportation and communication lead to ever greater movements of goods and people. Protecting an infrastructure that handles such an enormous volume of freight and passengers is clearly a gigantic task.

Transportation targets appeal to terrorists for many reasons. First, transportation is a major sector in any economy and a significant contributor to national growth. The global freight system, which is vulnerable at many points, is of particular concern because of the national and international consequences of a successful attack. International trade would be halted and economic growth throughout the globe would slow, imposing a heavy burden on all states, especially upon those least able to bear it.

Second, terrorists now seek to inflict as many casualties as possible. Transportation nodes—stations, subways, and airports—are therefore appealing targets. The March 2004 attacks on the Madrid train stations, where over 170 people were killed and many more injured, and the July 2005 attacks on London's underground system, which killed 56 people (including the four suicide bombers) and injured about 700, provide vivid and tragic proof of the appeal of these targets.

Third, transportation facilities are often national and international icons, and the demolition of a famous bridge or a well-known tunnel would possess great symbolic significance.

Effective transportation security presents a secondary positive aspect as an essential counter-terrorism tool. Terrorists have to travel to their targets with their weapons or to a place where they can obtain them. A secure transportation system can obviously limit the mobility of terrorists, an issue of growing concern to law enforcement agencies everywhere.

Effective transportation security can also increase the security of vehicles that can be, and sometimes

have been, used as weapons. The tragedy of September 11, 2001, in New York and Washington, D.C., was the result of airplanes transformed into missiles and fired into buildings. More common are truck bombs, which have been launched against intermodal terminals, bridges, tunnels, vessels in port, trains, and buses.

Terrorists are also exploring the potential of other weapons, including radioactive materials. The acquisition of 110 pounds (50 kilograms) of highly enriched uranium (HEU) would permit terrorists to assemble a nuclear weapon, albeit an inefficient one. However, building a bomb is a difficult task, even with the necessary materials and the technical know-how. More likely is an attack using a radiological dispersal device (RDD) that explodes and disseminates radioactive materials in a transportation facility or disperses such materials in powdered form, perhaps from a plane.

Even more likely are chemical and biological attacks, because terrorists can easily acquire numerous agents that cause diseases such as the plague, botulism, and smallpox. The deployment of a few grams of these microbes would cause death and create panic. Many other virulent toxins can be identified, some of which (such as sarin gas and anthrax) have actually been used. Each of these substances poses unique challenges that require particular countermeasures and responses, which also depend on the nature of contexts and resources.

Cyberattacks, which are commonplace, also pose a significant threat. These can take many forms. A specific database of a transportation owner/operator could be attacked in order to gain information, or an attacker could seek out a weakly defended pathway for access to a network in order to shut down service or to introduce harmful instructions. Attacks could be launched against highway traffic, train control centers and air traffic control systems, ports, power and telecommunications systems, and railroad signals. A successful attack that led to the derailment of a train loaded with chlorine in an urban area, for example, would have devastating consequences.

Globalization and Intermodalism

Since attacks against transportation systems can take many forms, safeguarding transportation systems is a challenging task. But two macro developments further compound the challenge.

Technological developments, particularly in the fields of transportation and communications, have made the world a smaller place. As distance and time have shrunk, an ever-growing flow of people and goods across national frontiers further accelerates the process of economic and financial integration. Today, companies produce in many countries, ship components from one subsidiary to another, distribute finished goods to markets in many countries, and use the transportation network as a warehousing system.

Safeguarding this system is no easy matter. First, sheer size creates difficulties. Container freight has grown exponentially in the few decades since its introduction. Today, about 90 percent of the world's cargo movements involve containers, and millions arrive at major seaports each year.

Second, the economic and technological integration that has been achieved has not been matched by an equal degree of political coordination and cooperation. There is a growing discrepancy between traditional borders and economic boundaries, which continue to expand outward as a result of various international trade agreements. Therefore, new questions have emerged to complicate the already complex and difficult issue of border security. Does the United States, for example, maintain inspection and verification rights at its own borders, or does it delegate them to the Mexican and Canadian government?

The situation at the international level is highly complex. International politics does not possess any central authority, let alone one that can enforce regulations and mandates. The international system is one in which all kinds of actors, states—international organizations, corporations, nongovernmental organizations, groups, and individuals (including terrorists and criminals)—strive to pursue opportunities and avoid danger.

Because the system is characterized by a lack of agreement on responsibility and overlapping claims to jurisdictional authority, national policy makers confront substantial challenges in such areas as maritime and aviation security. Organizations such as the International Civil Aviation Organization (ICAO) and the International Maritime Organization attempt to play a coordinating role, but issues of implementation remain. Coordinating all these international, transnational, and domestic actors and stakeholders is extremely difficult.

The second development is intermodalism, a recent development that integrates the different transportation modes into a seamless system and uses each mode for the purpose for which it is best suited. It has become a rapidly growing characteristic of transportation systems everywhere.

On the freight side, global freight now moves along a system that links the individual modes of highway, rail, and shipping, and that system is becoming even more integrated because of constant pressures to reduce costs by increasing productivity and reducing inefficiencies. Further, increased customer expectations of both freight and passenger systems extend beyond economic considerations to such areas as environmental impacts. Similarly, passenger systems are becoming increasingly interconnected; airports, for example, are now increasingly integrated with train and metro lines.

Each of these modes has its own approaches to security, so questions of coordination, which are always difficult even when one is dealing with only one mode, are further complicated by a variety of personnel and communication practices and technologies. Moreover, the decision-making structures are still commonly organized by modes, and the key private and public actors continue to think along modal lines, often nationally, an orientation that does not facilitate the implementation of appropriate policies to safeguard any transportation system. It is now essential to view transportation security from an intermodal or systems perspective and to be sensitive to the global reach of transportation systems.

Although transportation must be viewed globally and intermodally, it can be divided into two categories: passenger systems and freight systems. Though they are interrelated, they must be considered separately because each has distinct and separate features that present particular security problems.

Intermodal Passenger Systems

By their very nature, intermodal passenger systems (mass transit, rail, highways, aviation, and maritime) are especially vulnerable because each is complex, large in terms of the areas it covers and the number of people who utilize it, and designed to be easily accessible.

Mass transit. Although there have been several deadly attacks on passenger systems by suicide

bombers, the one on the Tokyo subway in May 1995 by terrorists who deployed sarin gas revealed the kinds of weaknesses that have often characterized passenger systems. These can be summarized as follows: (1) lack of an integrated structure; (2) poor and conflicting information reaching the key decision maker; (3) slow diagnosis and reaction times because subway officials were unprepared for this kind of attack; (4) first responders and hospitals were inadequately prepared; (5) a lack of resources including medicines and effective communications; and (6) poor communication between and among the first responders, their managers, and decision makers, and with the public.

Any attempt to increase the security of a passenger system must therefore take such factors into account. But these involve only the response to an attack. Securing a passenger system also requires (1) clearly defined goals and the use of risk assessment methodologies that link actions to potential threats and costs; (2) criteria identifying key assets and choke points such as bridges, intermodal terminals, and border crossings where their destruction could seriously impact the public welfare or have serious economic consequences; (3) standards for threat reduction at these points; (4) hardening infrastructure at critical points; (5) closed-circuit television (CCTV), biometrics, and other relevant technologies; (6) response plans to handle incidents, including direction and control, communications, and public information; and (7) security education and awareness programs for planners, managers, and operators and for the public.

Many such measures have been implemented to varying degrees in the United States and elsewhere. Additionally, in the United States, Visible Intermodal Protection and Response (VIPER) teams have been deployed at various mass-transit stations.

Highway and rail systems. Highways cover huge distances and encompass thousands of bridges and tunnels that are also prime terrorist targets. However, although it is possible to destroy bridges or tunnels and achieve a symbolic triumph, the damage is localized. Similarly, although difficult to protect, trains run along specific routes and can be controlled. If taken over by terrorists, for example, the train could be diverted from its original route. The same kinds of protective measures as for transit are relevant and could be deployed.

Aviation. Aviation is the passenger system that has received the most attention for many decades and to which most resources have been allocated. It shares many similarities with the surface systems in that it is large and complex and offers easy access. However, the numbers involved are small in comparison to the numbers of passengers using surface or underground rail in many locations, making it possible to screen all passengers and their baggage.

The tragic events of September 11, 2001, when hijacked planes destroyed the two World Trade Center towers in New York and damaged the Pentagon in Washington, led to the adoption of new, far-reaching measures in the United States and elsewhere. The most prominent of these has been extensive passenger screening at airports. However, this approach is extremely expensive, and it is not obvious that it is cost-effective. Tests have consistently revealed that it is still possible to smuggle weapons and explosives past the screeners. More important and effective are new measures such as the installation of reinforced cockpit doors, the deployment of armed marshals, and the arming of pilots to make a successful hijack highly improbable.

Additional measures that have been implemented in the United States and elsewhere include the appointment of federal security directors to all major airports, establishing controls on who can access various airport areas, and background checks of airport workers and staff. In the United States, the attempt to implement an advanced passenger profiling system (CAPPs II) proved quite controversial because it would incorporate private as well as public databases. Subsequently, the VIPER system of behavior profiling was implemented. Bomb detection equipment has also been widely installed.

Attacks can also, and have, come from outside the plane. Surface-to-air missiles, which are readily available throughout the world, pose a deadly threat to any plane because they can be fired from some distance away. How to deal with this threat remains controversial because of the high costs involved in equipping passenger planes with defensive technology.

Finally, general aviation—private planes that can be rented as well as the thousands that are owned by individuals and companies—also raises security concerns. The larger jets can be used as missiles and the smaller planes can disseminate radioactive or

other dangerous materials. Yet, these planes, despite various precautions, remain relatively accessible to terrorists.

Maritime. The first terrorist act against a cruise ship occurred in 1984, when the *Achille Lauro* was hijacked in the Mediterranean Sea. The threat remains, as evidenced by al Qaeda documents decoded in Germany in May 2012. Though cruise ships are attractive targets because of the large number of people involved and the high level of publicity that would be generated by an attack, a successful hijacking requires considerable resources and would have minimal impact economically.

Various measures have been widely adopted to counter such a threat, including baggage and store checks, screening and tracking passengers, and a requirement that U.S. ports be notified of passengers 36 hours prior to arrival. Some lines have initiated security training for crews and may have armed security personnel on board.

Intermodal Freight Systems

Surface transportation. Of all the millions of tons of freight that are carried daily by road, ship, and rail, the most important from a security standpoint are hazardous materials (HAZMAT), a wide-ranging category that includes chemicals, gases, and other materials that are explosive, flammable, toxic, infectious, or radioactive. The most common in the United States is chlorine, millions of tons of which are produced and transported by rail in pressurized tank cars. These present attractive targets because an exploding tank car (caused by an attached bomb) would release a toxic gas with devastating consequences.

Although freight rail security programs have been developed and implemented, numerous problems remain, including the large number of railcars, which may sit unguarded at rail yards; inadequately trained workers; and inadequate preparations for disaster response.

Air cargo. Passenger planes as well as cargo planes carry freight, and here serious issues deserve attention. Such measures as permitting cargo pilots to carry guns, utilizing armed guards on cargo flights, strengthening cockpit doors, and securing the cargo ramps by requiring everyone to undergo a background check all deserve attention. These should,

Passengers undergoing security checks in this highly visible screening area at the new Denver International Airport in 2005. Aviation security changes implemented after the terrorist attacks of September 11, 2001, have included the appointment of federal security directors to every major U.S. airport, improved controls over access to secure areas, and background checks of airport workers and staff. Other additions have included the use of the VIPER behavior profiling system and of bomb detection equipment.

however, be part of a risk-based, comprehensive cargo security plan with deadlines and targets.

Maritime cargo. Millions of containers and a considerable volume of other cargo enter the ports of the world annually. Checking each container or even a statistically significant percentage at a large port is an impossible task; it would bring commerce to a standstill.

Accordingly, the United States has established a number of programs designed to deal with this problem. The Container Security Initiative (CSI) screens cargo before it arrives at U.S. ports and the Customs-Trade Partnership Against Terrorism (C-TPAT) invites shippers to provide data concerning their manufacturing and logistical operations. In return, their goods are less likely to be inspected at the port of debarkation.

Both programs, however, face the problems of verifying the accuracy of vast amounts of information provided by the shippers (a problem aggravated by potential corruption and other forms of criminal activity) and of analyzing it in an efficient and timely manner, so that appropriate action can be taken in regard to high-risk cargo.

The enormous flow of goods aggravates the many security weaknesses inherent in any port's structure and operations, including accessibility by both land and water, the large numbers of stakeholders and workers, and extensive storage facilities. Such vulnerabilities can be minimized through the utilization of such technologies as electronic container seals, sensors to ensure that containers are not opened illegally, conducting background checks of all who access or work in the port and providing them with biometric identification cards, and

using electronics to track trucks and railcars. However, implanting such measures requires adequate financing and coordination by the diverse stakeholders involved.

Conclusion

The most effective way to enhance transportation security is to prevent an attack from occurring. Transportation security, therefore, must be viewed within a larger context—one that recognizes the significance of intelligence, foreign policy, and diplomacy, and is proactive rather than reactive. This means that transportation professionals must now acquire new skills and interact with national security policy makers at the highest levels. Given the need to deal with underlying causes of terrorism and the large overlap between transportation and other critical infrastructures, such coordination is essential.

In the end, however, it is the transportation community that must assume primary responsibility for ensuring that personal mobility and the movement of freight and goods continue as smoothly as possible; failure to do so would seriously hinder national development and future growth everywhere.

Shared Taxis

A shared taxi, also called a jitney, is vehicular transportation provided to multiple passengers, often on an informal and possibly on-demand basis. There are two major types of shared taxi systems: the jitney system, in which an unofficial vehicle (often a small van) provides service along a more-or-less regular route and for a standard fee, and a second type more analogous to a traditional taxi system and in which a group of people agree to share a vehicle (often a traditional taxicab) for a particular trip; in this type of shared taxi, different passengers may well have different starting and ending points.

Both methods of taxi sharing offer transportation that is more efficient than each passenger driving his or her own car, and more flexible than is typically provided by official, scheduled mass transportation, although they offer challenges in terms of safety. Both systems are in use all over the world today and are particularly useful in areas where the supply of transportation from official services does not meet the demands of passengers.

History

Shared taxis date back to the early days of the automobile. Although some see the roots of the jitney system in a streetcar strike in Phoenix, Arizona, in 1913, the first broad application of this system of transportation dates from 1914. In that year, partly as a way to make money during an economic downturn, automobile drivers in Los Angeles, California, began offering rides in their cars for the price of a nickel, or "jitney." Soon informal routes developed, often paralleling streetcar routes, and provided a transportation alternative to the streetcar

for people who did not own a car. A distance-based fare structure developed so that higher fares were charged for longer trips.

The jitney system became popular in Chicago in 1915, during a streetcar strike, when many people used shared cabs to get to Chicago's Loop (downtown). The Chicago system proved so popular that the city government tried to regulate it, creating assigned routes and requiring jitneys to carry signs with their prices and routes, but it was largely unsuccessful.

Although the jitney system rapidly spread across the country, the unplanned experiment in Chicago also showed one of the problems with replacing mass transit (streetcars) with relatively small-capacity automobiles in a densely packed urban area: extreme traffic congestion as large numbers of people tried to get around a relatively small geographic area more or less at the same time. The informal nature of the jitneys also raised issues about safety, the economic viability of the system, and, particularly in segregated areas, how to provide services to passengers of different races.

Present-Day Shared Taxi Systems

Two types of shared taxi systems are common today. In one, a system of small vans or similar vehicles provides service similar to that of municipal buses, along routes that are known to residents of the area, even if they are not officially recognized by the local government.

In the other, individuals choose to share a taxi from an airport or another starting point, perhaps by using a mobile app or Web site to find available transportation, but there is no expectation that the taxi will follow a similar route on each trip. Instead, the route is based on the needs of the particular group of passengers at the time.

The first type of shared system is common particularly in suburban areas, the less dense areas of large cities, and as feeder systems to official organized transportation systems in the central urban areas. For instance, Queens, a borough of New York City, has long had a system of "dollar vans" running along major streets and linking people to subway stations and other common destinations. A similar system exists in the northern New Jersey cities that are relatively close to New York City but inadequately served by official municipal transportation systems.

This type of shared taxi system is sometimes seen as threatening to official local transit, because passengers using the unofficial system are presumably being "siphoned off" from the official system, thus lowering ridership. Because official transit systems are relatively inflexible in terms of making route changes and often have higher operating costs because of administrative overhead, safety requirements, and other issues, the unofficial vans are often seen as unfair competition. In addition, because the unofficial vans are often largely unregulated, they may be seen as less safe. They also could pose a potential burden to the public if they do not carry sufficient insurance.

Some researchers have suggested that this type of shared taxi might be particularly useful in suburban areas, where traditional transit systems nearly always run at a deficit due to low population density. The relative flexibility of private providers offers an advantage in that they are likely to find the most efficient and profitable routes, although leaving an area entirely to the private sector could result in limited or no service for elderly or disabled residents, people in poverty, or those whose homes are too far from the profitable routes.

The second type of shared taxi service involves a group of passengers agreeing to share a taxi for one trip and splitting the cost of the ride. This type of shared service is common at major airports, where there may be a dispatcher or taxi marshal assigned to group passengers into cabs. Such systems are somewhat formalized when the transportation authority provides passengers with lists of fixed prices for various destinations, and the marshal may also be in charge of preventing unlicensed cabs from picking up passengers.

Mobile technology is now enabling people, taxi companies, and/or municipal governments to create online booking systems or cell phone applications to enable passengers to book a cab or enter their origin and destination points and find others who will be traveling along similar routes and are willing to share a cab.

New York City began allowing licensed taxi cabs (those ubiquitous yellow cabs) to provide shared rides in 2010. Passengers gathered at group taxi stands and organized themselves into cabs going to a common destination. However, the service proved unpopular, perhaps because a wide range of transportation options were already available in the city.

Shared taxis have been more successful in areas where there are fewer options, including suburban Montreal, Quebec, and Sun Prairie, Wisconsin; the latter is a small town near the state capital that has no municipal bus system but provides subsidies to private shared taxi services offering door-to-door transportation.

Ships

A ship is a watercraft used for the transport of cargo or passengers. Though "ship" originally referred to a sail-driven craft with a particular type of rigging, today it refers to any large watercraft. The difference between a ship and a boat is simply one of size, although there are some exceptions—riverboats, ferryboats, and submarines are considered boats regardless of size.

Ships are referred to in the female gender in the maritime trade, in casual use, and in some formal

style guides. Ships usually have individual names, and, despite the convention of a ship being female, the name may be female, gender-neutral, or male (e.g., military ships are often named for former presidents or generals).

Ships and boats are among the oldest forms of transportation, and their uses in fishing, whaling, and transportation of goods across waterways were key to the development of human civilization. Many early settlements were founded by seafaring people from other lands, and critical historical developments have been wrought by waves of such people introducing cultural and material novelties to new lands or colonizing them.

Among the host of colonizers who arrived by ship are the Vikings of the early Middle Ages, who sailed throughout Europe and far northern North America, and the Europeans who created trade routes and colonies throughout the world from the 15th century on. Marine travel was also critical in the development of scientific understanding of the world. As the sciences of navigation and mapmaking were being refined, the compass and optics were developed in support of sailing, and ship design evolved as understanding of mechanics improved. Ship travelers all over the world introduced their cultures to new ideas, new foods, and previously unknown forms of life.

The hull of a ship is the foundation of its architecture, and buoyancy is achieved by the hull displacing a greater weight of water than the weight of the ship. Ships do not glide on the surface of the water but, rather, sit upon the water with much of the ship submerged beneath what is visible. Compartments in the hull are used to hold ballast water, providing weight that helps stabilize the ship by making it bottom-heavy.

The foremost part of the hull is the bow, while the keel extends along the length of the ship at the bottom of the hull and provides stability and longitudinal strength. In the Anglo-American shipbuilding tradition, the construction of the ship begins with laying down the keel. Propulsion systems are usually mechanical today, with sail- and human-powered propulsion generally used only for small boats. Mechanical propulsion systems usually use a diesel engine to drive one or more propellers, for which there are numerous designs. Steering is accomplished by the lateral force enacted on the water by a rotating rudder.

Ship Classification

Many modern ships belong to a ship class, consisting of ships of a distinctly similar design, within a specific ship type. In the U.S. Navy, ship classes are named for the lead ship in the class, which, by extension, usually means the ship with the lowest hull number.

The Nimitz class of super-sized carriers consists of 10 nuclear-powered aircraft carriers, the lead ship of which is the USS *Nimitz*, named for Admiral Chester Nimitz, the Pacific fleet commander during World War II. Within that class are two subclasses, the Theodore Roosevelt class, which incorporated slight improvements on the original (1975) design of the class, and the Ronald Reagan class, which incorporated some of the features that were later used in the class that succeeded the Nimitz, the Gerald R. Ford class.

Merchant ships are classed by classification societies such as the American Bureau of Shipping, which employs engineers and surveyors to inspect ships and classify them according to factors including their structure, stability, and safety, with respect to their purpose. For this reason, merchant ship classes are often more descriptive than the Navy's, such as "oil tanker," or "mixed cargo carrier."

"Ice class" is a class notation that reflects the ship's ability to function amid sea ice. The American Bureau of Shipping includes a hierarchical set of ice classes, A5 through A0, followed by B0, C0, and D0, from strongest to weakest. The strength of the rating indicates the degree to which the hull has been strengthened to withstand pushing through sea ice.

Greater structural integrity is guaranteed through the use of scantlings-girders, bulkheads, and beams; and at the highest classes, the hull is fitted with sea bays and sea chests for seawater intake, as well as protection for the propellers and rudder (or use of azimuth thrusters). Fuel tanks also require heating to prevent fuel from becoming a gel at Arctic temperatures. Ice class ships include but are not necessarily icebreakers, which are ships specially shaped and powered to clear ice in order to make a path for merchant ships. Icebreakers are key to keeping trade routes traversable in the Arctic region.

There are a wide variety of ships built for special purposes, such as rescue boats, various types of research and survey vessels, fishing vessels, weather ships, and pilot boats. Naval ships are built

Canadian Coast Guard ship Louis S. St-Laurent and the U.S. Coast Guard cutter Healy in Arctic Ocean ice during a joint survey of the Arctic continental shelf on September 5, 2009.

in accordance with their purpose and relationship to combat. Generally speaking, commercial ships can be divided into two types: passenger ships and cargo ships. Passenger ships include ferries, ocean liners, and cruise ships, any of which may also carry a certain amount of freight or cargo, although they are not designed to do so as their primary purpose (and, so, they typically lack special cargo-handling equipment such as cranes).

Cargo ships come in various specialized types according to the type of cargo they are designed to transport, such as oil tankers or chemical tankers for liquid cargo, bulk carriers or general cargo ships for dry cargo, container ships designed to carry standardized shipping containers, and others. Today's modern cargo ships require properly designed ports, canals, and inland waterways to

facilitate their travel and docking, and specialized facilities for loading and unloading their freight.

Sidewalks

Sidewalks accommodate nonmotorized travel, which has become increasingly more important because of environmental and health-related problems of automobile-dependent societies. Therefore, accessible, safe, and comfortable sidewalk and crosswalk design is an essential component of a comprehensive transportation planning agenda.

The national standards for sidewalks and crosswalks are provided by the Americans with Disabilities Act (ADA) Accessibility Guidelines for Buildings and Facilities (ADAAG). The Institute of Transportation Engineers (ITE) and the American Association of State Highway and Transportation Officials (AASHTO) also provide recommendations.

Pedestrian presence in public rights-of-way requires access, safety, and amenities for comfort. Sidewalks and crosswalks are two areas of public rights-of-way that provide these conditions for the pedestrians. Access relates to circulation of all pedestrians with ease on sidewalks and while crossing a street. Safety refers to traffic safety and crime safety. Pedestrian amenities include landscape

elements, street furniture, streetscape amenities, public art, and "parklets" or small, park-like areas.

Access

For circulation of all pedestrians, the width without obstacles (clear width), grade, and surface quality of sidewalks are considered.

For an average person, the required clear width for standing is 1.5 to 2 feet, and for walking comfortably, it is 3 to 4 feet. For two people walking side-by-side, 5 feet of unobstructed width is required. For wheelchair access, 3 feet of unobstructed width is required on a public right-of-way. If the clear width is less than 5 feet on any route, a passing space with 5 feet of clear width must be provided at reasonable intervals, not exceeding 200 feet. A person with a service animal or a sighted guide uses 4 feet of width. Therefore, accessible sidewalks are a minimum of 5 feet wide on local streets in residential and commercial areas. In central business districts, the width of a sidewalk should be approximately 10 feet.

Grade is the degree of inclination of the slope parallel to the direction of travel. It is the ratio of the change in elevation to the distance covered. A running slope, which is the average slope along a continuous slope, should not exceed 1:20 (5 percent) with ramps not exceeding 1:12 (8.33 percent) where necessary. Cross-slope is the slope measured perpendicular to the direction of travel. It should be measured every 2 feet, which represents the stride of a person or the wheelbase of a wheelchair. The cross-slope of a sidewalk should not exceed 1:50 (2 percent).

The type of surface material on which people circulate is a matter of access, as well. Firm and stable surfaces, such as concrete, are preferable for durability. Slip-resistant surfaces are necessary for safety. Efficiency of movement for pedestrians or for people with disabilities is improved on firm, stable, and slip-resistant surfaces; on such surfaces, people spend their energy mainly for horizontal movement. Changes in level, which refer to the height changes between adjacent surfaces, are problematic for accessibility. Examples of level changes include curbs (without curb ramps), grooves in concrete, heaving, tree root infiltration, and small steps, among many others. Maximum vertical level change is one-quarter inch.

Grates are another example of level changes. A grate is a permeable framework of latticed or

parallel bars allowing liquids and small objects to go through. Maximum width of gaps on a grate is one-half inch in the direction of travel. The maximum gap at a rail flangeway is two and one-half inches.

Curb ramps, which have several components and types, are also crucial for access. There are five components of a curb ramp. (1) The landing is the part on the sidewalk at the top of a curb ramp. (2) The approach is the section adjacent to the landing on the sidewalk. (3) The ramp is the sloped transition between the street and the sidewalk. (4) The flare is the sloped transition between the ramp and the sidewalk. (5) The gutter is the dip along the edge between the street and the ramp. An accessible curb ramp has a ramp at least 3 feet wide and a 4-foot-wide landing in a perpendicular curb ramp form or a 5-foot-wide landing in a parallel curb ramp.

The four types of curb ramps are perpendicular, parallel, diagonal, and built-up. The perpendicular curb ramp is located within the border width, is oriented at a 90-degree angle to the curb line, and is usually installed in pairs at a corner. The diagonal curb ramp is located at the apex of the curb radius to serve both crossing directions at once. The parallel curb ramp, or an in-line curb ramp, is all or part of the sidewalk ramping down to a street crossing. The built-up curb ramp extends from the sidewalk with flared sides blending down to the street surface and blocking the gutter. Both parallel and built-up curb ramps are considered suitable for narrow sidewalks. A recent trend is to combine these curb ramps with partial or full curb extensions to improve the safety of crosswalks.

Crosswalks are particularly important for pedestrian access because crossing time and different types of crosswalks provide various levels of access and safety. A crosswalk is a designated passage for pedestrians to cross the street. Therefore, crossing time plays an important role in the efficiency of a crosswalk. The walking speed for an average adult is assumed to be 4 feet per second when signal timing is adjusted. However, for children, seniors, and people with disabilities, the walking speed goes down to 2 feet per second. Moreover, most people walk slower than 4 feet per second, even though it is the industry's standard.

Some crosswalk types provide better access and safety than others. Crosswalks are usually located at the intersection of two streets, but sometimes

in midblock. In either location, crosswalks may be marked or unmarked, although marked crosswalks provide better safety for pedestrians. Also, in either location, the accessibility and safety of crosswalks are enhanced with partial or full curb extensions. The curb extensions at the intersections are also known as neckdowns. The curb extensions are beneficial because they calm the traffic, shorten the crossing time and distance for pedestrians, and improve visibility for both drivers and pedestrians. Similarly, medians and islands provide refuge from the traffic for crossing pedestrians.

Medians separate opposing lanes of traffic; islands are protected spots for pedestrians on crosswalks to wait before they continue crossing. Also, in grade-separated crossings (that is, overpasses and underpasses), pedestrians and motor vehicles are allocated to different levels. The grade-separated crossings, however, provide poor mobility compared to other crosswalk types. When medians, islands, and crosswalks are raised only, their visibility increases without affecting mobility.

Safety

Traffic safety is addressed in sidewalk design through arrangement of different zones of sidewalks and traffic calming measures. There are three zones of a sidewalk: (1) the effective width or walking zone, where movement effectively takes place; (2) the shy zone, the shy distance, or building zone where pedestrians avoid walking due to proximity to buildings, retaining walls, fences, etc.; and (3) the curb zone, furniture zone, or planting strip where landscape elements, street furniture, and streetscape amenities are mostly placed. Sidewalk arrangements provide better protection for the pedestrians from traffic when the curb zone is between the walking zone and the road bed. Curbside parking enhances the traffic safety level of this arrangement.

Traffic calming measures include the curb extensions, road diets, raised crosswalks, speed bumps, use of the proper level of lighting at the crosswalks, effectively placed signage, and various types of beacons allowing pedestrian control for crossing. Curb extensions and road diets rely on slowing down the traffic by narrowing the road bed and/or the traffic lanes. Raised crosswalks and speed bumps help lower the speed of traffic. Lighting crosswalks adequately makes the crosswalks more visible to the drivers, which also slows down the traffic.

A curb extension, also known as a neckdown at an intersection, narrows Broadway as it approaches 33rd Street in Herald Square in New York City. Curb extensions can increase the safety and visibility of crosswalks, shorten crossing time, and calm traffic.

Signage and various types of beacons, such as a rectangular rapid-flash beacon and a pedestrian hybrid beacon, help increase the visibility of crosswalks and lower the speed of vehicles. A rectangular rapid-flash beacon uses rapidly flashing rectangular-shaped LED lights that are mounted on the crossing sign. Similarly, a pedestrian hybrid beacon is used at an unsignaled location with a marked crosswalk.

Crime prevention through environmental design (CPTED) addresses crime safety on sidewalks. The key concepts are territorial reinforcement and natural surveillance, as well as lighting for security.

Territorial reinforcement is having a sphere of influence around a person where territorial control is established. The familiarity with that territory and its users reinforces that territory in a way that a potential intruder would be discouraged. Along

the same line of thought, natural surveillance is designed to maximize visibility of publicly available spaces so that potential intruders are observable. Because of territorial reinforcement, the potential intruders are also recognizable. These concepts help designers create defensible sidewalks where high visibility and high control discourage a potential offender. Lighting for security is another way of achieving high visibility for the same purpose.

Pedestrian Amenities

Although they make a walkway more attractive and pleasant, pedestrian amenities are considered as obstacles and protruding objects from the perspective of accessibility because they may limit the clear width of a sidewalk by intruding into the walking zone. Therefore, the location of landscape elements, street furniture, streetscape amenities, and public art is crucial in the design of sidewalks.

Landscape elements include street trees and other plants that add visual and seasonally varying appeal to the sidewalks and help improve air quality. Yet, maintenance of landscape elements may be difficult and expensive. For visibility purposes, communities establish standards for the distances between intersections and trees. Vertical clearance and grates, which are used as tree guards, are other issues related to street trees. Landscape elements are usually placed in the curb zone.

Street furniture—such as benches, chairs, tables, kiosks, and transit stops and shelters—provides functionality, human scale, and definition. Most street furniture elements are fixed in place, although some of them may be movable. Coordination of street furniture placement improves their efficiency. They are also usually placed in the curb zone, although depending on the land use, some street furniture may be located in the building zone. For example, restaurants place tables and chairs in the building zone.

Streetscape amenities include street lights, signage poles, trash receptacles, newspaper racks, bollards (vertical posts), utility-related structures, public phones, parking meters, and fire hydrants. The location of streetscape amenities in relation to each other may make the pedestrian environment cluttered. Street lights are important to establish desired illumination levels for safety reasons. Location of street lights in relation to street trees affects the level of illumination because tree canopies may

block the street lights. Streetscape amenities are usually placed in the curb zone, as well.

Public art is another visually appealing pedestrian amenity, which also helps strengthen local identity. In addition to sculptures, murals on the walls or on crosswalks are especially useful as traffic calming measures.

Parklets are fast spreading as contemporary pedestrian amenities. A parklet is a small pedestrian space achieved by conversion of an automobile space into an activity area for pedestrians. They are on either commercial or residential streets. So far, implemented parklet examples have been built through conversion of several types of automobile spaces. One type of automobile space is parallel or diagonal parking spots on streets; another one is a traffic triangle, and a full lane. They accommodate a variety of pedestrian activities. Some parklets are built and maintained by businesses, such as cafés and restaurants. Some of them are outdoor exercise courts; some are for plants only, and some for sitting only.

Single-Occupant Vehicle Trips

Convenience and habit can be said to be powerful forces in human affairs. The phenomenon of single-occupant vehicle (SOV) trips offers abundant evidence to support this thesis. Culturally, the automobile has been promoted and marketed for approximately 100 years as an instrument of individualism, independence, self-gratification, and ego enhancement. By identifying with these potent qualities long ago, the automobile became an icon of mobile identity, one that could be interpreted as reinforcing its use in the single-occupant mode.

Structural Underpinning

It would be very difficult for many individuals to become habituated to perpetuating SOV trips if not for the vast edifice that has been constructed in major industrialized nations to support this ability and choice. Economies of scale had to be assembled in order to bring the prices of automobiles into the range of affordability for masses of people. Roadway networks had to be constructed and maintained. Fuel, parts, equipment, and services to support automotive culture had to be distributed to large and small population centers in every type of terrain and climate zone. Administrative, licensing, regulatory, and law enforcement agencies and staffs had to be concentrated and trained.

All of this meant taxes, fees, and funding channels had to be devised and implemented. And the industries of image-burnishing had to be enlisted, paid, and employed to promulgate the ideal of individual, liberated drivership.

Each of these elements has in fact occurred in many parts of the world. The number of vehicles in operation worldwide surpassed 1 billion in 2010, according to various researchers. About one-fourth of those were in the United States, where the ratio of cars to people has reached approximately eight

motor vehicles for every 10 people, exclusive of motorcycles and other two-wheelers.

The automotive social and physical support structure also extends to work arrangements. For all the discussion of the trend of telecommuting and all the investment in mass transit, fewer than 6 percent of workers use public transit to commute, according to the American Community Survey conducted by the U.S. Census Bureau—and almost 80 percent of Americans working outside their home drive to work alone.

Preference Patterns

It has been shown through extensive research that drivers consistently make SOV decisions based on convenience, a sense of reliability, flexibility, and general comfort and satisfaction. While many drivers who elect to operate in SOV mode have sampled the various carpool and public transportation options available to them in their vicinity, it takes little in the way of an unforeseen delay, dislocated schedule, or perceived safety risk to influence subsequent decisions toward the private vehicle option, and that most often leads in particular to an SOV trip.

Many drivers are aware of the cost trade-offs but are willing to make sacrifices in other parts of their household budgets in order to preserve their preferred SOV practices. Obviously, this route is easier for more affluent car owners.

Outside of the work commute—by far the most common use of a private car—the second most frequent use of private automobile travel is commuting to a school. Much as it can be for workplace decisions, dependence on the use of a car is a chief determining factor in the choice of educational venues to attend. A person or family can relocate to a desired neighborhood that may be distant from a preferred school—yet, without making any particularly inconvenient arrangements, the individual in question can still commute to that school by means of an SOV trip. From among other forms of discretionary travel mode selection, it is sometimes a personal lifestyle choice to travel alone by car—for example, when on a leisure trip.

Inducements and Incentives

Some local transportation authorities, parking operators, and institutional stakeholders offer inducements for their stakeholders, employees, or

members to doubleup, carpool, avail themselves of mass transit, or otherwise elect options other than SOV travel.

To take one example among a myriad of such programs, the University of Washington charges \$423 on a quarterly basis for SOV permits for faculty and staff (and slightly less for students) to utilize on-campus parking facilities. For the same price, a carpool group of three individuals can avail themselves of the same parking facilities—but they will split the cost three ways.

Alternately, the university promotes its U-PASS mass transit permit as a virtually free benefit component of its standard student activities fee; it has a nominal price of \$76 per quarter. U-PASS provides full-fare coverage on multiple mass transit systems and lines of service, discounted ride service on additional lines, and discounted carpool parking, vanpool fare credits, and discounts on bicycle safety equipment as well as at various merchants. In other words, the University of Washington has heavily disincentivized SOV travel as a choice of commuting mode among its student body.

Such programs may have a compelling impact over the long term, as collegial environments can tend to reinforce collective behavior. Even in the generally less congenial milieu of the workplace, employer subsidies of mass transit usage by employees can also help condition the individual to rely on mass modes of commuting as opposed to stepping back to SOV trips once such a subsidy is left behind as a result of job change or venue relocation.

Hybrids and HOV

It is widely considered that experimentation with high occupancy vehicle (HOV) lanes on highways have been less than an outstanding success in fostering the adoption of carpooling behavior by the great mass of commuters. HOV lanes do provide some congestion-relieving benefits under certain conditions on some highways. However, there are shortcomings to the technique, and quite often one outcome is greater congestion on the remaining lanes than there would otherwise be if the HOV lanes were opened to SOV travelers. Ironically, this is especially evident during peak rush hour times.

In some quarters, in the interest of environmental benefits among others, it has been proposed to permit hybrid-type SOVs to operate in HOV

lanes, under the reasoning that drivers should be rewarded for investing in hybrids and for the very real benefit that they deliver over regular internal combustion engine vehicles that make up almost the total volume of vehicles on the roadways.

At least one study, conducted during a recent 15-month period on segments of major commuter arteries in California, showed no negative impact on HOV lane operations or overall highway traffic flow by allowing hybrid SOVs to operate in the HOV lanes—even when the hybrids approached a threshold of approximately 20 percent of the total HOV-lane traffic. (The hybrids were identified by yellow stickers distributed free to some 85,000 owners of various models, such as the Toyota Prius.)

This somewhat lengthy experiment was conducted in part because the state transportation authorities in California had been considering implementing the hybrid-SOV-in-HOV proposal on a permanent and widespread basis. It ended, however, in mid-2011. Researchers and policy makers harbored the concern that SOV hybrids could one day in the not-too-distant future surpass the capacity of HOV lanes to sustain them, and a policy reversal at that point would be far more difficult to execute, as precedent would have been set and would have been operating for some years—never an ideal scenario for policy reversal.

The trial became more complicated, however, when the state launched another SOV-in-HOV program with free white stickers to 22,000 zero-emission, all-electric, or compressed natural gas vehicles—and then still another variation on the test, this one set to operate through January 2015, featuring free green stickers being given to up to 40,000 electric plug-in vehicles such as the Chevrolet Volt.

Smart Cars

Smart cars, referred to also as autonomous, self-driving, robotic, autopilot, driverless, auto-drive, automated guided vehicles (AGV), or iCars, are capable of driving by themselves using artificial intelligence and mechatronics (the integration of electronics, control, software, and mechanical engineering). While many of the cars on roads today have a degree of automation (for example, temporary auto-pilot functions, cruise control, adaptive headlamps, lane departure warning systems, and automatic parking), vehicles relying entirely upon automation (fully autonomous) are predicted to be on the market within the next decade.

The term *smart vehicles* refers to vehicles equipped with a level of automation or artificial

intelligence. Semi-autonomous vehicles require an operator, whereas a fully autonomous vehicle can handle all aspects of driving, maneuvering, and accident avoidance. The vehicle is able to completely manage itself from point A to point B, without any human intervention, regardless of the situations which arise. Vehicles equipped with artificial intelligence software have the ability to sense objects close to the vehicle and mimic the action that would usually be taken by a human.

Google has been working on smart cars since 2010. This sits logically with its work on mapping and software. Google's driverless car project maintains a test fleet of seven cars (one Audi TT and six Toyota Priuses) that has driven over 500,000 miles. Google and the automotive industry are developing robotic prototypes using wireless technology. The first benefit of smart cars is that they should be able to offer improved road safety and reduce traffic accidents, injuries, and deaths. In fact, Google estimates that robotic cars could reduce the number of road deaths each year significantly. The global total of road deaths was 1.24 million in 2011, 37,000 of which occurred in the United States, 27,375 across the European Union (EU), 143,000 in India, and over 70,000 in China. Robots, according to engineers, react faster than humans because they have 360-degree perception and do not get distracted, sleepy, or intoxicated.

Smart cars can drive more intelligently than non-autonomous cars. They can implement eco-driving techniques, which reduce consumption of gasoline and other finite fuels and, as a result, reduce costs to the car owner. In this way, smart cars are considered a positive addition to carbon reduction and climate change mitigation.

Futurist Randall Parker suggests that robotic cars will make electric cars more attractive and economically viable. He sets out three reasons for this. First, electric robotic vehicles can take themselves to recharge stations and batteries could then be smaller and cheaper. Second, electric robotic vehicles could carry more people per day because they could be routed from one individual to another, like a taxi, when a rider uses a mobile device to signal a need for a ride. This reduces vehicle miles traveled and increases productivity and efficiency for the vehicle. Last, electric robotic vehicles could park themselves at the periphery of urban areas until required. This reduces congestion and parking costs.

The autonomous car's smartness comes from a series of sensors that are positioned strategically about the vehicle. A rotating sensor on top of the car scans a minimum of 200 feet (61 meters) in all directions. This generates a precise three-dimensional map of the car's surroundings. The ability of the smart car to detect and react to moving obstacles such as other traffic, pedestrians, and traffic signals relies upon a camera adjacent to the rear-view mirror that communicates information to the car's onboard computer.

Cameras are used to, for example, distinguish lanes. Global positioning units are used to determine the car's location by getting information from satellites and ultrasound sensors to detect obstacles in front and to the back of the car; these are particularly important for parking. How a car drives and reacts can be programmed for different driving personalities—the programmed personality could be cautious and risk averse or confident and bullish—and the personality chosen would determine whether a car gives way to another vehicle, for example.

Benefits and Risks

While smart cars offer a number of benefits, they are not without limitations and risks. Smart cars operate through an intricate web of artificial intelligence, so inevitable faults can develop with the technology-causing accidents or damage. In addition, private maintenance of the robotic vehicle may be cost-prohibitive because of the high-level engineering and software technologies involved, which escalate costs.

The convenience of the vehicle may enable passengers to use their travel time in a way that increases their efficiency, but it could also result in complacency and over-reliance on automation, which could mask signs of faults or glitches. It was argued that smart cars may contribute rather than relieve congestion as owners send their cars off to do more tasks, and the owners themselves may grow less healthy if the cars' convenience discourages exercise.

A number of challenges lie ahead for smart cars. The car manufacturer Ford has made it clear that the main barrier, in addition to affordability issues, to commercialization of the autonomous car is customer acceptance. Trust in the technology seems to be the sticking point. Through a series

of clinics and polls, Ford has found that people are uncomfortable with the idea of surrendering control of their vehicle to a computer, although they are receptive to greater intelligence within the car, such as a collision warning for safety and automatic parallel parking. In an attempt to acclimate customers to automated vehicles, Ford has introduced the new Ford Fusion, which is the first affordable sedan to be equipped with a lane-keeping system.

The biggest unresolved issue to be addressed prior to mass commercialization of smart cars is liability. Individual states in the United States, namely Nevada, California and Florida, are already preparing themselves for the future uptake of smart cars by introducing legislative measures that allow autonomous vehicles to operate on public roads, but these do not address issues of who is legally responsible for an autonomous vehicle that has caused an accident or highway offense. Is it the owner of the vehicle, the manufacturer, or the software developer?

Potential solutions to the issue of liability vary but could include the introduction of laws limiting the liability of robotic manufacturers. Because of liability concerns in the United States, the European Union, and other countries with complex legal regimes, many in the automotive industry predict that China will become the first major market for smart cars.

A further challenge to the operation of robotic cars in current transport systems is the need for them to be able to coexist with cars driven by humans (that is, nonautonomous cars). Autonomous cars will be able to communicate with each other, but they will be less capable of determining or predicting the actions resulting from the more intuitive and improvisational driving techniques of humans. Some conversations around managing the coexistence of autonomous and non-autonomous vehicle technologies propose the development of special roadway lanes for smart cars. However, this poses planning, development, and land use issues and could trigger further discussion on the negative environmental effects of greater road construction.

The idea of self-driving cars as a means of reducing accidents and congestion has been around for a long time. One of the most popular exhibits at the 1939 New York World's Fair was Futurama, a

This rotating sensor installed on top of an autonomous Volkswagen Junior 2 in 2009 used 64 laser beams to scan the surroundings in all directions, collecting 1.3 million three-dimensional datapoints per second.

depiction of a city with cars remotely controlled by radio. In the 1980s and 1990s, the European Commission sponsored a program of research on automated driving called Prometheus. The Prometheus project on autonomous vehicles commenced in 1987 and ran until 1995. Outputs were the twin robot vehicles VITA-2 and VaMP developed for Mercedes-Benz by a team with the Bundeswehr University of Munich.

In the mid-2000s, the Pentagon's research arm, the Defense Advanced Research Projects Agency (DARPA), launched its Grand Challenges, offering prizes to inventors of driverless cars that did best at navigating a tricky course.

Commercialization

The commercialization of smart cars that are fully autonomous is just years away. The technology exists and is being robustly tested, particularly in Nevada and on autobahns in Germany. Researchers at Oxford University are testing the self-piloting of a Nissan Leaf controlled by an Apple iPad in the

dashboard. It is guided by a low-cost navigation system that assesses its surroundings using cameras and lasers built within the body. The iPad can issue a prompt to offer the driver the opportunity take the wheel and then switch back to autonomous mode by touching the screen.

The 2014 Mercedes-Benz S Class, revealed in May 2013, has all the technology built in to operate fully autonomously. However, due to outstanding legislative issues, the technology will be programmed not to operate, at least in the short term. Undoubtedly, legislators and administrations are tuned in across the globe to smart-car developments. The potential benefits appear to justify the costs of implementing and accommodating this forthcoming revolution in passenger road transport.

Smart Growth

The prevailing pattern of urban growth, particularly in the United States, is in the form of sprawling, auto-oriented, low-density development, mostly in the suburbs and outer edges of metropolitan regions. Beginning in the 1990s, proponents of smart growth sought to change this pattern of development by seeking ways to concentrate urban growth at higher densities and closer to the traditional urban core.

By definition, "smart growth" refers to those policies and planning strategies that build communities in a compact way, and with a variety of housing and transportation choices near employment, schools, shopping, and other amenities. Typically, the focus of smart growth is on managing urban development at a regional scale in ways that offer a better balance between where housing, amenities, and jobs are located within a metropolitan area. Thus far, the focus of smart growth policies has been the United States, although recently, an alliance of various organizations in the United Kingdom agreed on a set of principles promoting smart growth policies adapted to conditions in that country.

As an urban planning model, smart growth has a number of key goals. These include the following:

1. Developing mixed-use, dense, and walkable communities
2. Reinvesting in existing infrastructure in older communities
3. Promoting transit-oriented development that encourages the use of public transportation and reduces reliance on the automobile
4. Developing a range of housing choices and styles
5. Preserving open space, farmland, and environmentally sensitive areas
6. Enhancing a community's sense of place

Those who promote smart growth goals include environmentalists, urban planners, and some politicians and policy makers, as well as advocates of public transit and central-city living.

Smart growth communities are sometimes labeled new urbanist. Smart growth and New Urbanism are described synonymously, but they are in fact distinct. Smart growth originated out

a concern for the environment and is very policy driven and policy focused. New urbanism, on the other hand, is more design-oriented, originating from the fields of architecture, urban design, and physical planning.

New urbanists focus on changing the physical shape and orientation of communities to include sidewalks for walkability, a variety of housing styles, mixed-use development, and opportunities for the incorporation of public transit. The goals of smart growth and new urbanism are very similar but their approaches are quite different. New urbanists focus on community-scale planning and design options to create neotraditional-style developments. Smart growth advocates focus on introducing policies at a regional scale to guide compact development toward more central locations.

In this regard, strategies used in the promotion of smart growth include offering incentives such as density bonuses, grants, and funds for infrastructure provision in ways that encourage the market to intensify urban development in certain locations. Incentives are at the heart of smart growth policies. The following is an example of what considering the transfer of development rights (TDR) program means.

TDR programs are fairly recent market-based tools in the smart growth toolkit. These programs establish a transfer system where, a property owner sells his or her development rights, typically to a developer, who then uses these rights to build in a different location. The land from which the development rights are sold remains preserved from development with an easement. The location where the developer is allowed to build is referred to as the “receiving area.” The developer can build typically at high densities in these designated areas. The supply and demand for TDRs will depend on the profitability of development and the demand for higher density in designated receiving areas.

History of Smart Growth

The specific origin of the term *smart growth* is uncertain, but there were a number of important events that led to the establishment of smart growth principles as elements in urban and regional growth management. Each of these events took place in the mid-1990s. First, the American Planning Association (APA) produced an influential report in 1996 titled *Growing Smart Legislative*

Guide: Model Statutes for Planning and the Management of Change, offering governments “practical tools” to prevent urban sprawl and at the same time protect farmland and open space. The APA updated this guide in 2007.

The main audience for the *Growing Smart* report is state government officials, such as governors, state legislators, state legislative research staff, state planning agencies, and other state-level offices, as well as officials engaged in various aspects of land use planning and growth management. The APA’s *Growing Smart* guidebook offered a number of recommendations related to state zoning reform and state regulatory responsibility. While zoning and land use regulation remains the primary domain of local government, the *Growing Smart* guidebook encouraged state-level interventions.

In a similar manner and around the same time, the Natural Resources Defense Council (NRDC), a nonprofit environmental advocacy organization, produced the *Toolkit for Smart Growth*. The Surface Transportation Policy Project (STPP) was an important partner in the development of NRDC’s smart growth toolkit. This nonprofit organization promotes an increase in the availability of varied transportation choices, including walking and public transit. The *Toolkit for Smart Growth* focused on ways to promote higher-density development, increased transportation choice, and other smart growth planning initiatives.

In 1996, the U.S. Environmental Protection Agency (EPA) established a network of various agencies interested in smart growth development. This was another key event in the history of smart growth. The EPA is a federal agency charged with monitoring, setting standards, and regulating to protect the natural environment. Smart growth planning and policy aims to protect the environment from any negative impacts of urban development and sprawl.

According to many research studies, sprawling development creates environmental problems, including increased air pollution; higher energy consumption; loss of open space, farmland, and species habitat; shifts in patterns of local and regional species diversity; storm-water runoff impacting stream ecosystems and water quality; and increased risk of flooding. The EPA, through its Office of Policy, established a clearinghouse of news, research, presentations, and other resources

to provide information on smart growth related topics to the public, government agencies, scholars, and students. A number of publications are produced through the EPA's Smart Growth Network, including a 100-page primer titled *Getting to Smart Growth: 100 Policies for Implementation*, which offers concrete techniques to implement smart growth principles across different jurisdictions. The Smart Growth Network aims to encourage the development of smart growth policies across the United States.

Finally, in 1997, the state of Maryland passed the Neighborhood Conservation and Smart Growth Act. After the legislation was passed, Democratic Governor Parris Glendening established an Office of Smart Growth that was housed in the governor's office. It was the first gubernatorial-level "smart growth office" in the nation. Maryland's law is designed to target development in certain areas close to the urban core, and at the same time includes land-preservation strategies to prevent development on the outer edges of the region. Specifically, Maryland's Priority Funding Area program, a central element of the law, allows counties and local jurisdictions to receive funding for public infrastructure, such as public sewer, water, schools, and housing, only if development occurs in designated growth areas and preexisting communities.

The Rural Legacy program, a second key element in the law, establishes a funding stream for buying the development rights of farmland, open space, and environmentally sensitive areas with the explicit goal of preserving farmland and green fields. Over the years, Maryland's smart growth program has won numerous awards and accolades, yet there is still some controversy over the program's ability to prevent sprawl.

According to the Maryland Department of Planning, land consumption by large-lot development is still a problem. The agency found that between 1990 and 2004, the highest rate of land consumption by residential development occurred outside its Priority Funding Areas. Since Maryland's law was passed in 1997, smart growth programs have emerged in other U.S. states. According to a study conducted by the American Planning Association in 2002, one-quarter of all states had strong-to-moderate smart growth policies. These states include Delaware, Florida, Georgia, Maryland, New Jersey, Oregon, Pennsylvania, Rhode Island,

Tennessee, Vermont, Washington, and Wisconsin. There are now examples of smart growth programs in a variety of places.

Examples of Smart Growth

Arizona's Governor Jan Brewer recently established the state's Growth Cabinet. In 2006, this group of 13 state agencies in Arizona came together to consider issues of water and air quality as they developed ways to integrate land use and infrastructure planning across the state. An extensive component of Arizona's smart growth strategy included an extension of the Valley Metro project, a light rail project in the Phoenix metropolitan area. In 2008, the first 20 miles of the light rail started accepting passengers.

In 2001, then Michigan Governor Jennifer Granholm introduced a number of smart growth policies to slow down the rate of land consumption in agricultural and open space areas by suburbanization. Part of the strategy revolved around revitalizing older suburbs and inner cities. Michigan's Cool Cities program aimed to redevelop cities and the Fix It First policy focused on redeveloping existing infrastructure rather than developing anew.

The Illinois state legislature passed the Green Neighborhood Grant Act in 2007, offering financial incentives for the development of more energy-efficient, environmentally sustainable, and pedestrian-friendly communities. The state also offers incentives to developers who create workforce housing and locate housing near major employers. Many of the state-level examples of smart growth initiatives are policy-oriented strategies that offer tax incentives, subsidies, or public investments to encourage development in particular locations and/or of a particular type.

There are literally thousands of individual community-level examples of smart growth initiatives. Each year, the EPA offers a National Award for Smart Growth Achievement to those communities that introduce and implement smart growth strategies in new and innovative ways. The EPA created the National Award for Smart Growth Achievement in 2002. From 2002 to 2013, the agency received 809 applications from 50 states, the District of Columbia, and Puerto Rico.

Examples of the winners include Lancaster, California, for redeveloping its downtown corridor with mixed-use development and housing, and business

and streetscape redevelopment; Portsmouth, Virginia, for conducting a major overhaul of its land use regulations to become more pedestrian friendly; and San Francisco, California, for developing a \$50 million revolving fund for loans to invest in affordable, transit-oriented housing development. Many of the local-level examples can focus on the design elements associated with smart growth, including the development of more walkable streetscapes, mixed-use developments, and transit-oriented planned communities.

Criticisms of Smart Growth

A study of Maryland's smart growth program in 2009 suggests that it has largely been unsuccessful at preventing sprawl in the state. The researchers state that "[t]here is no evidence after 10 years that [Maryland's Priority Funding Area policy] ha[s] had any effect on development patterns." The researchers found that after Maryland's smart growth legislation passed in 1997, the number of parcels developed outside the Priority Funding Areas increased, an effect the legislation is supposed to prevent.

Other studies of Maryland's law found that although most urban development that happened after the law passed did occur inside Priority Funding Areas, this was the case even before the law. The question therefore remains whether the law had any impact at all on the pattern of urban growth in the state. Some critics argue that part of the difficulty with implementing successful smart growth planning at the state level is that it requires alignment of local goals with state objectives. This is often not the case. Growth management plans are often voluntary at the local level. If local governments do not want to fully embrace smart growth initiatives, then smart growth planning will not happen. Some critics suggest that smart growth is unlikely to be effective as long as local governments maintain exclusive power over local zoning and land use.

In other cases, critics of smart growth believe it increases land values and renders housing more unaffordable. Because smart growth policies limit growth in certain areas, the supply of land for residential development is reduced, causing land values to rise and housing to become more expensive. This, critics argue, has a negative impact on poor and minority families. These critics advocate a more market-based approach where government has less

Lancaster, California, won an award for excellence in smart growth from the U.S. Environmental Protection Agency in 2012 for the redevelopment of its downtown focusing on Lancaster Boulevard, shown here after completion of the project.

involvement in managing where urban development happens.

The Future of Smart Growth

The planning and policy initiatives behind smart growth have in many ways been deepened and expanded to include concerns with issues of sustainability and climate change. Since smart growth first emerged in the 1990s, the conversation about suburban sprawl has focused on how it connects to problems such as the energy crisis and global warming. Attempts to establish links between automobile use and greenhouse gas emissions have energized the debate over urban form and the need for more compact transit-oriented development.

Smart growth has always had a tone of environmentalism; for example, the impact of urban development on the Chesapeake Bay was of importance in the political debate over smart growth legislation in Maryland. But, with jurisdictions seeking ways to achieve emissions-reduction goals, smart growth development is becoming an increasingly viable

policy strategy. Households are concerned about rising energy prices, too, and they are seeking new ways to reduce transportation costs.

Also, and maybe more importantly, demographic shifts mean that there is a potential market for more compact, mixed-use urban-style development. Household sizes are getting smaller, reducing the demand for large single-family housing. All this means that the rationale for implementing smart growth policy is energized and bolstered. The smart growth framework is likely to remain an important element of urban planning as people consider sustainable solutions to future urban growth.

The Dutch smart highway was designed by Daan Roosegaarde and Heijmans Infrastructure, whose designs were awarded the 2012 Best Future Concept award in the Dutch Design Awards. The designs will be implemented in the Netherlands in phases from 2012 through 2018.

The first stage, adopted in North Brabant in the southern Netherlands, consists of glow-in-the-dark lane markers that charge up with sunlight during daylight hours and glow for up to 10 hours at night, brightly enough to provide a glow along the contours of the road. Used in areas without pedestrians, where further illumination is not needed, this eliminates the need for energy-intensive electric streetlights. Other concepts submitted by Roosegaarde include streetlights powered by the wind of passing cars, which could be used for illuminating street signage.

Future features include dynamic paint, which responds to temperature changes in order to warn drivers of slippery or icy driving conditions by displaying warning signals on the road surface. For example, in the concept design portfolio, freezing temperatures cause a snowflake pattern to become visible on the road surface. A similar warning system triggered by wind conditions is expected to be implemented in 2018.

One of the most talked-about features of the Dutch smart highway is the priority induction lane. Inspired by the third rail of railway systems, which provides electricity to trains capable of drawing from it, the induction lane is a traffic lane reserved for electric vehicles and capable of charging them via magnetic induction as they pass across it. Similar induction methods are already in use to power vehicles elsewhere, including vehicles developed in South Korea by the Korea Advanced Institute of Science and Technology as part of Seoul's efforts to become the world's leading city in green technology design and implementation.

Many of Roosegaarde's innovations are energy conscious, which is a common theme in smart highway discussions. Just as the "smart grid" of electricity delivery infrastructure improves efficiency and shortens repair time to save on energy costs, smart highway designs often focus on both fuel efficiency (as with the induction lane of Roosegaarde's) and the electricity use of roadside infrastructure.

Since the worldwide financial crisis of 2008, streetlight usage has been an area where some local

Smart Highways

Smart highways implement recent technology to provide features that improve driving. A broad category, the "smart highway" has been used to refer to automated highway systems and other intelligent transportation systems, as well as the Netherlands' recent safer highway design.

communities have sought to reduce their expenditures. Jacksonville, Florida, and Highland Park, Michigan, have both turned off substantial numbers of streetlights, or limited their use to certain hours, in an attempt to cut costs.

In addition to Roosegarde's wind-powered streetlight, there is the possibility of using the vibrations of cars to produce electricity (called piezoelectricity) to power lights and other roadside infrastructure. The California Energy Commission has approved a plan to explore the use of piezoelectric materials in this context. Such energy-gathering methods can be used for purposes other than illumination as well, such as automated bridge deicing in response to temperature changes.

In 2012, the Federal Highway Administration approved a grant for electrical engineer Scott Brusaw's proposal to design a solar-powered parking lot. Parking lots can neither make do with the minimal illumination of glow in the dark markers (since by their nature they host significant pedestrian presence), nor do they invite the high speeds necessary to power lights with the wind or pressure of passing traffic. Brusaw's proposal is to provide nighttime lighting using light-emitting diodes (LEDs) powered by solar cells. The use of LEDs improves the energy efficiency and allows for an easily configurable display that could display warnings or other important information. Solar panels could also be used to display advertising in order to defray costs.

Smart highway designs have been developed at the same time that driverless cars, also called self-driving, autonomous, or robotic cars, have become a reality. An area of research interest for decades, driverless cars have seen rapid development in the 21st century, sometimes piggybacking on the development of driver-assistance technologies such as automated parallel parking and adaptive cruise control. While not yet available, or even planned, commercially, driverless cars in the near future could be used both for passenger transport (either by their owners or as a taxi service) and for the delivery of goods. An automated highway system has been proposed in tandem with this eventuality.

In such a system, dedicated roads or road lanes would be used exclusively by driverless cars, which could communicate with one another through systems either required to be included in such cars or provided by the highway itself. Such communication would include information on speed, location, and

destination, giving the highway and/or the cars the ability to manage traffic for maximum efficiency. For instance, a smart intersection like one developed at the University of Texas would use no traffic lights, instead managing driverless traffic by manipulating speeds of the vehicles so that each car making a turn arrives at the intersection and is able to turn immediately, without another car being in its path.

While such communication systems are necessary for driverless cars, they could still be useful for human-operated cars and potentially incorporated on normal roads. Just as adaptive cruise control maintains a target speed under normal circumstances (which itself involves responding to road conditions) but reduces or increases that speed in order to avoid collisions, similar systems could be installed in automobiles to respond to triggers from a smart highway that would adjust speed or suggest a lane change to the driver in order to better manage the highway's traffic.

Traffic Management

A number of traffic jams are caused or worsened by the inability of drivers past the first few cars in the jam to perceive the conditions causing the jam, and so they cannot make anticipatory adjustments such as lane changes or detours. Roadway signs have been used in some areas to convey some amount of information but usually do little more than estimate the delay time and warn of a lane closure.

Smart highways could also manage traffic in response to emergency conditions, including weather events and evacuation routes, spills, and the rerouting of lanes in order to better accommodate emergency response vehicles. Just as systems like EZ-Pass automatically bill tolls to an account as the car equipped with the EZ-Pass rolls through a toll booth lane, a smart highway system can automatically deduct tolls without needing traffic to ever slow down, and could even divide tolls into more discrete increments based on usage, if that suited the needs of the community.

Smart highways could provide map information to vehicles, which could include nearby gas stations, mechanics, accommodations, and emergency assistance, as well as advertisements for businesses, which could help defray the costs of highways while providing more personalized billboard messages.

Of course, smart highways could also be used to monitor traffic violations such as speeding, reckless

driving, and other enforcement measures. Speed limits could also be enforced.

Accident Avoidance and Security

The Department of Transportation believes most car accidents are avoidable; smart highways could assist in avoiding them. Even smart highway signs, which notify drivers of accidents ahead or of stalled cars, would significantly impact both the number of accidents and the severity of the accidents that occur. In particular, the number of large multi-vehicle accidents could be curtailed.

Security applications of smart highways are considerable. Automatic license plate number recognition by digital camera is fairly simple, but if smart highways were widespread, license plates could be replaced or supplemented by symbols intended to be read by digital devices. This could enable automatic ticketing for speeding or other easily identified violations, or alert nearby police about erratic driving and other dangerous conditions that may require a response. Further, such technologies could provide homeland security authorities with information about transportation and transit patterns.

Highways could potentially be built to detect accidents as they occur, summoning help to the scene while also adjusting roadside signage to prevent a pileup. Integration with in-vehicle call systems (such as General Motors' OnStar) could collect information about passenger safety following an accident even before responders arrive. Separately, simple devices such as inductive loops embedded in the road could provide an accurate count of vehicle traffic on a given route to assist in transportation planning.

Smart highway design is supported by the Intelligent Transportation Society (ITS) of America, established in 1991 to advocate the development of smart highways in the interest of greater safety and sustainability. The U.S. group is instrumental in organizing the ITS World Congress, which pursues advocacy at the global scale, as well as maintaining state chapters in each of the 50 U.S. states.

Smog

The word *smog*, derived from the combination of the words *smoke* and *fog*, came into use in the early 1900s. Smog appears as a light brown blanket of air over heavily populated or industrial areas, although wind may blow smog out into suburban or rural areas. Requiring neither smoke nor fog, smog is a photochemical reaction in which air polluted with hydrocarbons and oxides of nitrogen, particularly from automobile exhaust, interacts with ultraviolet radiation from the sun, creating ozone (O₃). Thus, smog is more prolific in the summertime when temperatures rise and the days are longer. Sulfurous smog, as occurs with the burning of coal or other fossil fuels, increases with dampness.

Environmental Impacts

There are many health and environmental impacts resulting from smog. Negative health effects of smog include eye irritation, asthma, bronchitis, pneumonia, and respiratory distress. When lead exposure, most commonly resulting from resuspension of lead-contaminated soil, is included as a component of smog particulates, increased likelihood of learning disabilities exists. High levels of smog, often signaled by ozone warnings, can cause lung damage in healthy people and create further distress among people with lung and respiratory illnesses. Chronic heart disease and cancer may occur as the result of long-term exposure to high levels of airborne particulates.

In addition to its unpleasant appearance, smog produces many environmental effects. It reduces visibility and its color can be viewable from many miles away. The U.S. Forest Service has documented smog-related damage to trees and moss in

Smog seen across Tiananmen Square in Beijing, China, in 2006. As of 2013, smog levels in some Chinese cities had surpassed safe levels for their inhabitants. While the World Health Organization sets a safe limit for concentrations of $PM_{2.5}$ (the airborne particulates that pose the largest health risk) at 25 micrograms per cubic meter, the level had risen as high as 993 micrograms per cubic meter in Beijing in January 2013. Levels surpassing 600 micrograms per cubic meter were also seen in Shanghai in December 2013.

Pacific Northwest forests. In China, pollution-causing smog is so thick and widespread that it can be viewed from space in the sense that the smog blocks telescope views of the landscape.

Impacts of Industrialization

Particle pollution, also referred to as particulate matter, is a mixture of solids and liquid droplets that form both directly, as a result of pollutants released into the air, and indirectly, as pollutants combine in the atmosphere with other pollutants. Particulate matter that is less than 10 micrometers (PM_{10}) are smaller than the width of a human hair and can enter the lungs creating severe health problems. PM_{10} are coarse dust particles created by crushing and grinding as created through construction. Fine particles, less than 2.5 micrometers ($PM_{2.5}$), are so small that they cannot be seen by the human eye,

but they are detectable with an electron microscope. $PM_{2.5}$ sources include combustion emissions, burning, and some industrial processes.

In China, now an industrialized world leader and economic powerhouse, smog has reached toxic levels. In January 2013 official measures of $PM_{2.5}$, the fine airborne particulates that pose the largest health risk, rose to as high as 993 micrograms per cubic meter in Beijing. Twenty-five micrograms per cubic meter is the limit that is considered humane and still safe according to the World Health Organization (WHO). Air purifiers and face masks are largely unavailable due to skyrocketing demand in the hazy environment. This danger became renowned worldwide when many athletes participating in the 2008 Beijing Olympics trained in Japan rather than in the toxic capital city of China. China is hoping to make enough advances

in controlling pollution to win their bid for the 2022 Winter Olympic Games.

While paling in comparison to the severity of the levels of pollutants found in China, in the United States in 2013, nine of the top 10 smog-producing cities were in the western United States, with Washington D.C./Baltimore being the lone exception. Los Angeles had the highest number of smog/ozone days of the 277 metropolitan areas measured, with a weighted average of 81.8 high-ozone days. Ozone, a colorless, odorless gas consisting principally of nitrogen oxides and volatile organic compounds, is aggravated by carbon monoxide. The weighted average included 205 orange ozone days (unhealthy for people with respiratory illnesses), 10 red ozone days (unhealthy for healthy people), and three purple ozone days (very unhealthy for all). While ozone levels in these top 10 cities is high, the average number of days of high smog alerts decreased from 1996 to 2011, the span of years measured, by two months or more (60 plus days, in some cases).

Inequality

While the negative health impacts of smog do not discriminate, there is inequality in the likelihood of being directly affected by smog. Smog is most dense in heavily concentrated urban areas, where there also tends to be a higher concentration of minority residents and people in poverty. Incidences of asthma and other forms of respiratory distress are elevated in these areas with heightened levels of pollution, and are further exacerbated by stress and exposure to violence. African Americans are three times more likely than are whites to be hospitalized for asthma, with the Centers for Disease Control and Prevention (CDC) reporting that asthma rates for African American children increased 50 percent from 2001 to 2009. Exposure to environmental pollutants, colloquially smog, was listed as a primary contributor to the raging increase.

People who are poor are often unable to control their environment due to a lack of resources such as education and legal access. For example, Altgeld Gardens, an impoverished African American neighborhood on the South Side of Chicago referred to as a minefield of toxic hazards, has a disproportionate number of Chicago's toxic facilities as well as one of the highest cancer rates in the United States. The dilapidated housing project was

built on top of a former landfill, with problems such as approximately 70 percent of residents experiencing respiratory infection intensified by literally tons of pollutants from a nearby sludge plant, a steel mill, a paint company, a huge incinerator, and an 80-foot-high landfill.

Similarly, in Chester, Pennsylvania, whose population is approximately 70 percent African American, five of seven countywide waste facility permits are granted. Chester and Altgeld Gardens became dumping targets not specifically because the communities were predominantly African American but rather because community members have neither the financial means nor the political know-how to stop companies from siting facilities there.

Reducing Smog

There are a number of ways that people can work individually and collectively to reduce smog:

- *Drive less:* Trucks and automobiles produce a significant portion of smog. In 2001, drivers in Los Angeles contributed an average of 65 pounds of smog per person per year. The worst offenders, though, were Louisville, Kentucky, and Oklahoma City, Oklahoma, each contributing an average of 137 pounds of smog per person that year. While still very polluted with smog, restrictive state emissions standards contributed to Los Angeles' relatively low truck and automobile emissions.
- *Use alternate transportation:* By carpooling, walking, or biking, people can prevent some of the automobiles from polluting the environment and contributing to smog. When buses and trains are full, these modes of transportation produce fewer pollutants than do individuals driving in cars.
- *Stop idling:* When automobile engines idle for at least 30 seconds, more fuel is burned than if the engine were turned off and restarted. Turning off the engine wastes less fuel and gas money, as well as reducing smog.
- *Be aware:* Many local news organizations post warnings when smog/ozone is at a dangerous level for humans. People can also sign up for smog alerts from local or

regional associations, such as the Georgia Department of Transportation's Clean Air Campaign and the Southwest Ohio Air Quality Agency.

While smog is an ugly reality worldwide, there is evidence that individual and collective efforts are helping alleviate the levels of pollutants in the air. Through continued efforts, smog could become an infrequent occurrence in the future.

Social Equity and Discrimination in Transportation

Discrimination in transportation was rarely explicitly considered in transportation policy, at least in the United States, until the mid-1990s. Historians have noted that urban highway construction projects disproportionately affected low-income and minority communities beginning in the mid-1950s and only tailed off as new urban highway construction was curtailed during the 1970s. Despite this history, transportation professionals have often viewed their profession as one that improves the transportation options of the public without regard to race or social class. This understanding was challenged in the early 1990s when the frame of environmental justice was applied to transportation planning.

Legislative Background in the United States

Despite the history of urban highway construction disproportionately impacting low-income neighborhoods (sometimes explicitly in conjunction with slum clearance projects), much commentary about transportation—particularly highway projects or other road improvements—often asserts that public transport benefits everybody equally. This understanding has been increasingly challenged from a social equity perspective and arguably is no longer the majority perspective among transportation planners and government officials. This change can be at least in part attributed to the rise of the environmental justice perspective in the transportation sector.

The environmental justice movement investigates issues of equity and whether minority and low-income neighborhoods are bearing disproportionate environmental risk. The early environmental justice movement largely focused on toxic waste dumps and industrial pollutants affecting minority neighborhoods, but this frame was expanded in the 1990s to include the effects of transportation projects on minority and low-income communities, such as highway construction projects through inner-city neighborhoods or Native American lands, as documented by R. Bullard and G. Johnson in 1997. Among issues that led to several civil

rights court cases was whether transit providers were favoring rail investments that served predominantly white, middle-class commuters at the expense of low-income and minority bus patrons.

One significant action took place in 1994 when the Los Angeles Bus Riders Union and the Labor/Community Strategy Center sued the Los Angeles Metropolitan Transit Authority (MTA), alleging that the MTA's fare policies and rail construction programs disproportionately affected local transit dependents. The plaintiffs argued that the MTA was systematically undermining bus service, which served minority and low-income riders, to fund construction of its subway and light rail system, which had been designed to service primarily higher-income areas and tourist destinations. The parties eventually reached a settlement in which the MTA agreed to improve local bus service. The success of the plaintiffs' lawsuit led to a much broader investigation of the distribution of benefits and costs of various urban and regional transportation plans.

U.S. federal surface transportation law, particularly the then-current Intermodal Surface Transportation Efficiency Act (ISTEA), specifically called for metropolitan planning organizations to develop regional plans that were in compliance with Title VI of the Civil Rights Act. The act forbids transportation agencies from discriminating on the bases of race, color, or national origin. There was no federal guidance to direct planners on how to assess environmental justice impacts on low-income and minority populations, although a federal response was forthcoming.

President Bill Clinton signed Executive Order (EO) 12898 in 1994 calling on all federal agencies to specifically analyze how their decisions were affecting minority and low-income populations and to try to avoid disproportionate adverse effects on these groups. This EO can be considered the first step toward mainstreaming the concept of environmental justice into federal decision-making processes. Interim guidance to evaluate (and avoid) disproportionate adverse effects was provided by the Federal Highway Administration, Federal Transit Administration (FTA), and the Environmental Protection Agency (EPA) between 1995 and 1998, with the first stand-alone FTA circular on environmental justice published in August 2012 (FTA C 4703.1).

Although such findings were relatively uncommon, in 1999 the EPA found two regional planning

agencies, the Northwestern Indiana Regional Planning Commission and the Charlotte Area Transit System, to be out of compliance with EO 12898. The agencies were issued corrective actions and required to improve their examination of environmental justice in their long-range planning processes. In consequence, regional planning agencies expanded the types of transportation outcomes they measured and paid more attention to how costs and benefits were distributed across their regions and whether there were clear patterns that would indicate low-income residents or minority neighborhoods were uniquely disadvantaged. Nonetheless, it is still the case that within the United States, there is a wide variation in terms of how each planning agency measures equity and environmental justice—both in the types of measures examined and the rigor of the analysis. While planning agencies outside the United States have begun to consider issues of equity while developing plans, the administrative requirements are generally higher in the United States than elsewhere.

Analysis of Impacts

One difficulty in generating such guidance is that there are multiple definitions of social equity. Some draw more on horizontal equity, asserting that people should generally be treated equally, relatively to their ability to pay. In particular, user-pays systems assume that users of a transportation system and/or those who benefit from a particular facility should be primarily responsible for paying for the system. Some theorists contend that user-pays is hard to achieve in transportation precisely because there are so many positive and negative externalities, even across modes. Another standard is proportional equity, which asserts that the wealthy should pay more than the poor because they are better able to bear the burden of financing transportation systems and government functions more generally. Progressive taxes are based on the concept of proportional equity.

The FTA does not clearly ground its guidance in any particular equity framework, though its emphasis is on ensuring that disadvantaged groups are not clearly adversely impacted compared to the rest of the population, suggesting these rules are primarily based on maintaining horizontal equity. The FTA recommends using geographic units of analysis, so an area may be treated for the

purposes of analysis as a low-income or minority neighborhood. The benefits and social costs of carrying out a particular transportation plan or building transportation infrastructure are then assessed at these various neighborhood levels. A project may proceed if the disadvantaged neighborhood does not face disproportionate adverse impacts relative to non-disadvantaged neighborhoods (although negative impacts can also be balanced against strong positive benefits in deciding on the merits of the project).

There are clear limitations with this approach as it examines impacts on an aggregate basis, ignoring social equity considerations of individual low-income persons living in a neighborhood filled with middle-class households. Furthermore, as Paul Mohai (1995, 2008) and other researchers have pointed out, drawing different geographic boundaries and changing the reference categories can lead to different findings of adverse impact. Some activists believe that the institutionalization of environmental justice by the government has turned this into a technical issue driven by technocrats that shuts out neighborhood advocates. Without minimizing the limitations of the proposed approach, these analyses are focused on long-term impacts of transportation decision making; a more aggregate approach is acceptable and perhaps may be the only feasible approach for undertaking such analyses. The fact that the federal government takes social equity issues into consideration in transportation planning is a considerable and perhaps remarkable shift away from the planning approach of the 1950s and 1960s.

Space Travel, Commercial

Humankind truly entered the Space Age in 1957 when the Soviet Union launched a capsule called *Sputnik* into Earth orbit. The size of a basketball, the silvery *Sputnik* did little but emit a steady tracking beep. Nevertheless, it ignited the Space Race between the United States and the Soviet Union that broke open the new realms of space.

The two countries vied for a number of firsts in space: first object in space (*Sputnik*); first man in space (Yuri Gagarin, Soviet); first spacewalk (Alexei Leonov, Soviet); first multivehicle rendezvous and docking (Gemini program, United States); first manned lunar orbit (United States, *Apollo 8*), and first lunar landing (United States, *Apollo 11*).

One can argue that the missions of the Space Race were in fact commercial, for the National Aeronautics and Space Administration (NASA)

hired out the manufacture of essential components to private industries. Lockheed, for example, made the Apollo spacecraft; Grumman made the lunar module (LM) for manned moon missions. However, in the purest sense, they were not commercial. NASA and the Soviet space agency drew astronauts and cosmonauts from their country's military branches. Most American astronauts had been fighter pilots; many were air aces from the Korean War. Not until Harrison Schmidt, a geologist, went to the moon in *Apollo 17* in 1972, did a true civilian go into space.

Paid Space Passengers or Space Tourists

U.S. space shuttle missions, active from 1981 to 2011, brought the first chance for something like real commercial spaceflight. First, NASA began allowing members of the European Space Agency (ESA) on flights, and space contractor McDonnell Douglas paid for one of its engineers to fly on a shuttle. Then, NASA accepted congressional advocates of manned spaceflight to ride along on shuttle missions. Senator Jake Garn (R-Utah) and Representative Bill Nelson (D-Florida) made flights in 1985 and 1986, respectively. The civilians went aloft as "mission specialists," meaning they received limited training in only certain fields, nothing like the pilot training of regular astronauts. In the cases of the flying congressmen, their mission was publicity.

NASA attempted to validate its civilians in space program with the Teacher in Space effort. Elementary school teacher Christa McAuliffe was to present lessons from space to students on Earth via satellite links. McAuliffe and her six crewmates died, however, in the *Challenger* explosion in January 1986. NASA was about to resurrect the civilians-in-space program in 2003 by sending a journalist on a shuttle flight. It scuttled any further civilian plans when the *Columbia* broke up on reentry on February 1, 2003, killing its crew.

Meanwhile, the Russian Federal Space Agency and some U.S.-based private companies, such as Space Adventures, began facilitating passenger flights to the old Soviet MIR space station, and later the International Space Station (ISS). Most of those passengers rode on Russian Soyuz spacecraft. After all, American space shuttle missions ended in 2011, so any Americans in space are also getting there via the Russian Soyuz fleet, with NASA paying Russia

for the rides. In April 2013, NASA signed a deal for the Russian Federal Space Agency to take six Americans into space aboard Soyuz crafts between 2013 and 2017. NASA will pay an incredible \$70 million per ride.

Private Cargo, Public Engines

Early in the days of spaceflight, the U.S. Congress passed and President John F. Kennedy signed the U.S. Communications Satellite Act of 1962. It allowed NASA rockets to place privately owned communications satellites into orbit. While the act generated debate, it was little more than what the U.S. government had done to facilitate railroad travel across the American West. As early as the 1850s, the federal government acknowledged that a transcontinental railroad was necessary to link the eastern United States with western states. It also acknowledged that private railroads should do the work, but a project of that magnitude required resources and capital that only the federal government could muster. When Congress passed the Transcontinental Railroad Bill in 1862, the government agreed to subsidize railroads with grants of land, rights-of-way, and cash.

A century later, the Communications Satellite Act did much the same thing. Private companies would fund the satellites themselves, but the federal government would use its rockets and growing skill at orbital mechanics to place the satellites in the proper position to bounce, or relay, telephone and television signals. The Bell Telephone system funded the first private launch under the program. Bell Labs built *Telstar 1* and *Telstar 2*, which U.S. Delta rockets boosted into orbit in 1962 and 1963, respectively. (The satellites so caught the public fancy that an instrumental pop song, simply called "Telstar," climbed up the charts.) Long out of use, the satellites remain in orbit.

The United States, the Soviet Union, and later the Russian Federation continued to place private satellites in orbit in the 1960s and 1970s. In 1980, the European Space Agency (ESA) got into the private space cargo field with its Ariane rockets.

Encouraging Commerce and Privatization

In February 1988, President Ronald Reagan signed the Commercial Space Launch Act. It pledged the United States to legislation and policies that would make space available to private companies. It said

the United States would begin seeking launch opportunities from private companies, thus encouraging the private sector to develop its own boosters.

As further incentive, Reagan put the private sector, and to some degree, the world, on notice that the United States was not going to keep its reusable space transport, the shuttle, in service indefinitely. Though the shuttles remained in service until 2011, NASA had planned to decommission them as early as 2005.

In 1990, President George H.W. Bush signed the Launch Services Purchase Act. It effectively took the federal space agency out of the satellite launching business, putting the burden of continued satellite placement squarely on the shoulders of private industry.

In 2005, President George W. Bush announced the Constellation program, which would return Americans to the moon in phased operations. Constellation would involve Ares boosters (with detachable, reusable primary boosters, technology from the shuttle program) and Orion crew and service modules that looked much like the central components of the Apollo vehicles. NASA designers, in fact, called Orion “Apollo on steroids.” Bush said Constellation would re-establish American presence in space and lay the groundwork for further explorations, even to Mars.

In reality, it was simply an attempt by Bush to recapture the magic of Apollo and rescue NASA from the doldrums of the quarter-century-old space shuttle program. NASA, however, could never settle on a feasible cost estimate for Constellation.

When Barack Obama became the U.S. president in 2009, he authorized a Human Spaceflight Plans Committee (later known as the Augustine Committee) to review the Constellation program. The committee reported that Constellation was wildly behind schedule and over budget. Obama cancelled it, much to the chagrin of manned spaceflight advocates, including Neil Armstrong, the first man to walk on the moon.

Obama said he was not against the program in its entirety, but he wanted a program with more imagination (such as going directly to Mars or exploring asteroids) and did not want to waste time boosting astronauts to space stations in low-Earth orbit, which was a foundation of Constellation. Thus, Obama continued the general trend in U.S. spaceflight of letting NASA handle the dangerous edge of new space

exploration and handing over well-established space practices to the private sector.

Boom in Commercial Space Companies

In 2002, entrepreneur Elon Musk founded the space cargo company SpaceX. In 2006, it was one of two companies to which NASA awarded a Commercial Orbital Transportation Service contract to subsidize a private venture to ferry cargo to the International Space Station.

In 2012, SpaceX’s unmanned Dragon cargo craft successfully docked with the ISS and delivered cargo. The mission proved that private enterprise could enter orbit and rendezvous and dock with another spacecraft. NASA spent many Gemini flights in the mid-1960s learning those maneuvers. SpaceX Dragon proved the validity of NASA passing on its learned skills to the private sector.

As of 2013, 25 private international companies were developing space cargo and transport businesses; four were planning space stations; 16 were planning launch vehicles; 24 were planning moon-landing missions (one of which was named Golden Spike, a term that harkens back to the public/private character of the first transcontinental railroad); five were planning to mine the moon or near-Earth asteroids; and one, Mars One, was fund-raising and taking applications for married couples to go on a long-term mission to Mars. Many of those burgeoning companies were members of the Commercial Spaceflight Federation. The federation is an umbrella organization designed to facilitate interface with NASA or other space agencies.

X-Prize

As with anything commercial, money drives the goal. Exploration, new technologies, and medical advances may all be ultimate goals, as well, but financial incentives often get things moving. Such is the thinking behind the X-Prize, organized and funded (with partners) by the Exploration Prize Group, founded in 1995.

The first X-Prize incentive, \$10 million in cooperation with Ansari, would go to the team that could build and fly a craft with three people to a height of 60 miles (100 kilometers). They also had to accomplish the feat twice in two weeks. The winners were a team from Scaled Composites headed by Burt Rutan, a famed aerospace engineer whose Voyager long-distance aircraft flew around the world in nine

SpaceX's Dragon cargo craft docking with the International Space Station on March 3, 2013. It successfully delivered its cargo and stayed for three weeks. As of 2013, 25 private companies were developing space cargo and transport businesses.

days in 1986 without stopping or refueling. Rutan's SpaceShipOne claimed the Ansari prize in 2004. The successful mission helped set off the rush for private spaceflight achievements.

In 2009, Armadillo Aerospace and Masten Space Systems claimed \$2 million in a Northrop Grumman lunar lander X-Prize challenge. The mission was to build a rocket-powered vertical takeoff and landing (VTOL) craft that could demonstrate, repeatedly, on Earth the same type of landings and lift offs that a lunar mission would require.

As of 2013, Google had partnered with X-Prize to offer a \$30 million prize (the largest yet offered) to a team that could successfully land a robot on the moon, have it travel at least 500 feet, and then successfully transmit images and data back to Earth. NASA sweetened the pot, offering another \$30 million in contracts to the team if it accomplished a list of NASA-prescribed scientific objectives.

Manned Private Spaceflight

With the high price of Russian space tickets for American astronauts, and no small amount of glory that will come to whoever gets U.S. manned spaceflight moving again, private manned missions will not long lag behind unmanned flights.

On April 29, 2013, Virgin Galactic's SpaceShipTwo (also designed by Rutan's Scaled Composites) successfully completed an engine test that boosted the craft. SpaceShipTwo was hauled aloft by a mother ship, WhiteKnightTwo, which let it go at 48,000 feet. SpaceShipTwo then successfully finished its climb to 55,000 feet and achieved a speed of Mach 1.2. It then returned to a base on the floor of the Mojave Desert.

Virgin Galactic founder Richard Branson anticipated passenger flights on ships similar to SpaceShipTwo would begin after more rounds of engine testing in 2013 and 2014. Prices for suborbital trips would start around \$250,000 each, and then begin to drop after Virgin Galactic carried 1,000 passengers. SpaceShipTwo is still something of a tourist draw; it is not expected to do much for exploration or science. Nevertheless, it should prove that private carriers can safely ferry passengers without spaceflight training back and forth from space.

Others, such as Mars One, hope to prove the viability of private space-faring companies in true exploration. In April 2013, Mars One began taking applications for people to go on the first mission. Spaceflight training and experience were not necessary. In two weeks' time, Mars One had 78,000 applicants competing for four mission slots. Mars One hopes to land those four on Mars in 2023, then land others over two years as the basis of a permanent Martian colony.

Spatial Equity Analysis

Spatial equity analysis examines the fair allocation of public resources within units of government at the local, regional, and national levels. Distribution of public investments is considered fair when it is needs based irrespective of the demographic and socioeconomic profiles of each community.

Some of these distributions, of course, go to transportation investments, to the extent that historic developments in each locale have resulted in the separation of different land uses. Thus, transportation funds are needed for travel for a variety of reasons, such as commuting from and to work, traveling from and to a school, making shopping and business trips, visiting a doctor, and so forth.

It is relevant to examine, for example, whether a particular transit investment would assist the employability status of central-city minority workers facing housing segregation in the face of the suburbanization of entry-level jobs in the manufacturing or services sectors of the economy. In this case, the analysis may examine whether the minority community's welfare is improved with respect to job accessibility, commuting duration, and earnings.

A careful analysis could also determine, in this context, that longer commuting distances among workers of a particular racial group were not the result of housing segregation but rather a result of selective migration among members of that racial

group, who may have chosen to live farther away from jobs as a trade-off for better access to quality education for their children.

Another possible investigation may be concerned with how minorities' welfare varies geographically, or by gender, age, race and ethnicity, and education attainment. For example, one question could be whether employment security of female workers from minority communities is the effect of job retention (i.e., tenure with the same employer) or of employment retention (i.e., keeping jobs but with different employers), possibly with a trend toward upward mobility.

The next question might be, does vehicle access increase employment retention, or, more importantly, how many job opportunities can be accessed by a private vehicle (versus public transit systems) within reasonable travel time? Finally, do female minorities with a high school diploma, when given the appropriate accessibility and location opportunities, enjoy increased job retention?

A Case Study Example

In a planning study of the Chicago metropolitan area, authors examined in depth the transportation component of the welfare-to-work problem and provided strong support for the spatial mismatch hypothesis facing welfare clients and the unemployed. The study found the following:

- The spatial distribution of welfare clients and entry-level jobs imposed challenges for transit service providers because clients and jobs were dispersed throughout the metropolitan area.
- Welfare clients were likely to face significant difficulties in accessing jobs because of long distances and their need to access jobs through heavily congested urban areas, which resulted in extremely high door-to-door travel times between residential origins and job destinations, whether trips were by private automobile or existing transit services.
- There were wide variations in the travel times to job destinations from different neighborhoods. Some neighborhoods were relatively close to a large number of entry-level jobs, while others were rather far, and competition for the few

conveniently located jobs among many welfare clients made the transportation challenge much greater.

- Tremendous variations existed within the Chicago metropolitan area regarding spatial competition for jobs.
- Physical proximity to a job did not necessarily imply an increased opportunity for employment (i.e., if there are a large number of individuals in close proximity competing for the same job, there may be little benefit from physical proximity). In fact, the level of job accessibility in the Chicago central business district (at the time, close to 13 percent of all entry-level job openings) for welfare clients was lower than in many other areas in the region.
- Job stability in terms of full-time or part-time employment, as well as the length of job retention, appeared to be related to access to private transportation.

Transportation and Environmental Justice

Federal mandates dictate that land use and transportation analyses in state departments of transportation (DOTs) and metropolitan planning organizations (MPOs) consider the three core principles of environmental justice: (1) to avoid, minimize, or mitigate disproportionately high and adverse human health and environmental effects, including social and economic effects, on minority populations and low-income populations; (2) to ensure the full and fair participation by all potentially affected communities in the transportation decision-making process; and (3) to prevent the denial of, reduction in, or significant delay in the receipt of benefits by minority and low-income populations.

Spatial Mismatch Research

The main question for spatial mismatch research is whether the suburbanization of jobs and the serious limitation on black residential choice have acted together to create a surplus of workers relative to the number of available jobs within inner-city neighborhoods. Empirical research has sought to identify factors that contribute toward such disparities.

Such research has verified the continuation, albeit at a slower pace, of the suburbanization of

population and jobs since World War II; the changing distributions of job skills and worker skills; the segmentation of urban labor markets; the inability of black residents to follow the suburbanization of employment; the over-representation of blacks in central cities; the commuting disparities between blacks and whites; the poor access to job opportunities for blacks; the concentration of unemployment, low income, and poverty in central cities; and the residential inertia of blacks in poor areas. In view of the empirical research, theoretical developments have proposed several underlying mechanisms for such spatial disparities:

- The efficiency of job search may decrease with distance to jobs. Workers may obtain less information about distant job opportunities while firms resort to local recruiting methods, such as ads in local newspapers or “help wanted” signs not seen by distant workers.
- Incentives may be too low for workers residing far away from jobs to search intensively. For instance, when housing prices are very low at a distance from jobs, unemployed workers may feel less pressure to find a job in order to pay their rent. Alternatively, if the search costs are much higher for distant workers, then they may be discouraged and search less intensively.
- Workers may refuse jobs that involve particularly long commutes because commuting to that job would be too costly in view of the proposed wage. They may instead prefer to search for job opportunities in the vicinity of their neighborhood. As a result, workers may restrict their spatial search horizon.
- Inadequate transportation can exacerbate both search and commuting costs, amplifying the issues just listed.
- Employers in distant or suburban areas may discriminate against residentially segregated workers because of the stigma or prejudice associated with their residential location. Employers may hold the view that, on average, inner city residents are less productive or more likely to be criminal (statistical discrimination).

- Employers may refuse to hire or may pay lower wages to distant workers because commuting long distances makes them less productive (for example, they are more tired or more likely to be absent).
- Employers may believe their white local customers are unwilling to have contact with minority worker, and thus discriminate against minority workers (customer discrimination).

Job Access and Reverse Commute Programs

Employment transportation services were developed to provide access to jobs for people who otherwise would have few transportation options, either because public transportation is not available to their jobs or employment-supportive destinations (for example, day care, schools, job training, job search, etc.) or because they cannot afford to own and operate a private vehicle.

Employment transportation services include traditional fixed-route buses or demand-responsive services operated by local transit agencies; rideshare programs, shuttles, or charter services provided by nonprofit organizations, employers, or employment agencies; information services and mobility brokers that link information on jobs with transportation to those jobs; and car programs that fund ownership and use of private vehicles by low-income workers.

Employment transportation services provide valuable services to users. The services are being appropriately targeted and the individuals who use them are greatly dependent on them. Although program costs are high, benefits to the users are high, as well, and are likely to persist over time.

Empirical analysis has shown that it is not likely that many users will stay in the transit system over the long term, but that the temporary lift that these services provide is likely to make a significant difference in the users' lives and their work. Moreover, nonusers and society in general benefit because of potential alternative uses of tax dollars and avoidance of societal costs of private automobiles that users might otherwise have taken.

The negative impacts on local labor markets are likely to cancel some of these nonuser and societal benefits, but, because these negative impacts are dependent on local unemployment rates, the nonuser benefits from these services are ultimately likely to depend on economic cycles.

Accessibility Measures

The development of accessibility measures is important because it relates directly to the assessment of labor markets' accessibility, a central issue in spatial-equity analysis. In this context, the concept of accessibility has received numerous operational definitions in order to derive various measures and indicators, including (1) accessibility measures as a function of the transportation available to individuals, the temporal and spatial distribution of activities, and the social and economic roles of individuals that determine when, where, and for how long they must pursue different activities; and (2) accessibility measures to evaluate the availability and quality of basic services and alternative transportation modes at the neighborhood level. These accessibility measures represent how easy or difficult it is to reach needed or desired destinations, depending on where they are located and how those locations are served by a transportation system.

In addition, three types of accessibility measures have been used in practice:

1. The simplest type to operationalize consists of cumulative accessibility measures. These measures count the number of opportunities reached within a given distance, and give an indicator of the choices available to residents.
2. Gravity-based measures weight the amount of activity at different destinations by a cost function and the available opportunities in other destinations.
3. The final type derives accessibility from random-utility theory.

Overall, accessibility indicators used in spatial equity analysis are multidimensional in nature, using information from the transportation sector (for example, origins and destinations of trips, travel times, and costs), housing (for example, location of low-income people and affordable housing, crime rates, etc.), and economic development (for example, location of entry-level jobs, day-care centers, etc.) as input. Using such core multisector data, composite indicators and indices can be derived (for example, accessibility to day care, hospitals, jobs, one-stop centers, schools, and affordable housing locations; indices of transportation barriers

for low-income populations; neighborhood quality indices; and indices for job growth and unemployment.). In this regard, the accessibility problem can be frequently cast within the general framework of multiple-criteria decision-making methods.

Data Issues

Data used in spatial equity analysis are collected for different administrative purposes in the public sector (for example, to formulate policies and programs, to allocate government funds, and for business decisions in the private sector of the economy). Such data are usually available for analysis at different geographic scales (for example, census tract, ZIP code, county, etc.) and temporal scales (for example, different times of day, days of the week, etc.), thereby requiring careful statistical handling to alleviate various inconsistencies and error propagation. More spatio-temporal statistical issues emerge when aggregated data are analyzed together with individual personal or household data from surveys in multilevel analysis.

There are instances in spatial equity analysis where the linking of separate databases developed independently of one another becomes critical. In such cases, there are several data quality control criteria for the integrated database that should be satisfied before the analysis can proceed:

1. Does the database include all the attributes required?
2. Do key variables have values?
3. Are the data spatially and temporally consistent?
4. Does the integrated database add value above and beyond its individual database components?
5. Have the data been updated?
6. How accurate are the data elements?
7. Is there an adequate documentation of the data and the metadata?
8. Are the data easily accessible and unrestricted for use with standard equipment and software?

Speed Laws and Enforcement

Speed limits are the most common method for managing traffic speed. The current U.S. framework for setting speed limits was developed in the 1920s and 1930s. Speed limits in the United States have traditionally been the responsibility of individual states. State statutes specify speed limits that generally apply to different road types or geographic areas. In the mid-1970s, however, Congress established the National Maximum Speed Limit by withholding highway funds from states that maintained speed limits greater than the 55 miles per hour (mph). The requirement was loosened for rural interstates in 1987 and repealed in 1995. As of today, 35 states have speed limits of 70 mph or higher on some portion of their roadway systems.

In many states, the maximum speed limit that state or local authorities can establish depends on whether the road is a rural or urban interstate, a non-interstate limited-access highway, or another type of road. (Limited-access highways are multiple-lane roads with restricted access via exit and entrance ramps, rather than intersections.) The limited-access highways that make up the national interstate highway system are divided into urban and rural sections, based on population density figures from the U.S. Census Bureau.

State laws set maximum speed limits for each type of road and land use (urban or rural). Legal maximum speed limits also can be established for special situations such as school zones. The posted speed limit for a particular road or section of a road can be below the maximum speed limit allowed, however, if the local or state agency in charge of the road decides a lower limit is warranted. In this case, the state and most local governments have the authority to set speed limits on the basis of an engineering study. These studies usually take into consideration such factors as operating speeds of free-flowing vehicles, crash experience, roadside development, roadway geometry, and parking and pedestrian activity levels before concluding at what speed the posted limit should be set.

As of 2010, most states have increased the maximum posted speed limit above 55 mph for passenger vehicles, trucks, or both. Currently, only three states and the District of Columbia have maximum posted speed limits of 55 mph or lower for cars. One state has established a maximum posted speed limit of 80 mph, 11 states have established maximum posted speed limits of 75 mph, and another 19 have established maximum posted speed limits of 70 mph.

Driver Attitudes

A survey was conducted in 1998 for the U.S. Department of Transportation's National Highway Traffic Safety Administration (after the repeal of the 55 mph limit) on speeding and other unsafe driving behaviors. Some of the findings, not surprisingly, were as follows: there is an inverse relationship between the tendency to pass and age; three drivers in five (60 percent) felt that they often got impatient with slower drivers; and one driver in three (33 percent) said that they "try to get where I am going as fast as I can."

Approximately half of all the drivers in the study reported keeping up with faster traffic, and almost one-third reported being more likely to pass other drivers than to be passed. Both of these driving behaviors decreased with age. In general, positive feelings toward speeding decreased with age. However, agreement with the statement "I worry a lot about having a crash" also decreased with age. Drivers said that the major factors in determining the speed at which they drive were weather conditions, the posted speed limit, and type of road. A large

proportion of drivers felt it was safe to speed in certain situations (not in areas where children, playgrounds, or schools were located). Yet, three drivers in 10 felt speeding was a factor in at least 75 percent of fatal crashes, and two-thirds felt speeding was involved in at least 50 percent of all fatal crashes.

Speed Laws

Most U.S. states have adopted speeding laws that are aligned with the National Highway Traffic Safety Administration's (NHTSA) guidelines and regulations. The following are explanations for some of these:

- *Basic speed rule:* This rule requires vehicle operators to drive at a speed that is reasonable and prudent. As a corollary to this rule, state laws usually provide that every person shall drive at a safe and appropriate speed when special hazards exist with respect to pedestrians or other traffic or by reason of weather or highway conditions.
- *Minimum speed rule:* This rule prohibits a person from operating a motor vehicle at such a slow speed as to impede the normal and reasonable movement of traffic, unless when reduced speed is necessary for safe operation or compliance with law.
- *Racing on the highway:* This is usually defined as driving any vehicle in any race, speed competition or contest, drag race or acceleration contest, test of physical endurance, exhibition of speed or acceleration, or for the purpose of making a speed record.
- *Reckless driving:* This is generally defined as driving any vehicle in willful or wanton disregard for the safety of persons or property. (Speed is not necessarily a factor in this offense.)
- *Posted (maximum) speed limit:* State laws may allow authorities to specify different speed limits on all or selected highways (or portions thereof) either for various times of the day or for various types of vehicles.
- *Automated speed enforcement:* A number of states authorize the use of imaging technology by law enforcement to determine if a violation of the speed law has occurred. Legislative provisions vary widely regarding this issue, state to state.

- *Commercial motor vehicle (CMV) operators:* Generally among the states, a commercial motor vehicle is defined as a vehicle designed to carry passengers or property and has a gross vehicle weight of 26,000 pounds or more, is designed to transport 16 or more persons, or is transporting hazardous materials that require such vehicle be placarded in accordance with state or federal laws.

Highway Accident Data

According to the Insurance Institute for Highway Safety (IIHS) and the Highway Loss Data Institute, in 2011 a total of 9,944 deaths, or nearly one-third of all motor vehicle fatalities in the United States, occurred in speed-related crashes. Speed has a major impact on the number of crashes and injury severity, because it influences the risk of crashes and crash injuries in three basic ways: (1) it increases the distance a vehicle travels from the time a driver detects an emergency to the time the driver reacts, (2) it increases the distance needed to stop a vehicle once the driver starts to brake, and (3) it increases the crash energy exponentially. For example, when impact speed increases from 40 to 60 mph (a 50 percent increase), the energy that needs to be managed increases by 125 percent.

In a high-speed crash, a passenger vehicle is subjected to forces so severe that the vehicle structure cannot withstand the force of the crash. As crash speeds get very high, restraint systems such as airbags and safety belts cannot keep the forces on occupants below severe injury levels. There are limits to the amount of crash energy that can be managed by even the most recently designed vehicles—even with restraint systems and roadway hardware such as barriers and airbags. The higher the speed, the higher the likelihood that these limits will be exceeded in crashes.

The Highway Loss Data Institute studies and other research show that deaths on rural interstates increased 25 to 30 percent when states began to raise speed limits from 55 to 65 mph in 1987. In 1989, about two-thirds of this increase, or 400 deaths, was attributed to increased speed, and the rest to increased travel. A 1999 institute study of the effects of the 1995 repeal of the National Maximum Speed Limit indicated this trend had continued. The institute estimated a 15 percent increase

in fatalities on interstates and freeways in 24 states that raised speed limits.

A 2002 study also evaluated the effects of increasing rural interstate speed limits from 65 mph to either 70 or 75 mph. States that increased speed limits to 75 mph experienced 38 percent more deaths per million vehicle miles traveled than expected, an estimated 780 more deaths. States that increased speed limits to 70 mph experienced a 35 percent increase, resulting in approximately 1,100 more deaths. And, a 2009 study examining the long-term effects of the 1995 repeal of the national speed limit found a 3 percent increase in road fatalities attributable to higher speed limits on all road types, with the highest increase of 9 percent on rural interstates. It was estimated that 12,545 deaths were attributed to increases in speed limits across the United States between 1995 and 2005.

Although there is no definitive research showing crash effects associated with posting lower speed limits for large trucks, many safety experts favor differential limits because large trucks require much longer distances than cars to stop. Lower speed limits for trucks make stopping distances of trucks closer to those of lighter vehicles. Slower truck speeds also allow passenger vehicle drivers to pass trucks more easily.

The Insurance Institute for Highway Safety (IIHS) published research in 1991 that found that lower speed limits for trucks on 65 mph highways reduced the proportion of those traveling faster than 70 mph without increasing variation among vehicle speeds. The percentage of trucks traveling faster than 70 mph was twice as large in states with uniform 65 mph limits as it was in states with different passenger vehicle (65 mph) and large truck (55 mph) speed limits.

Sport Utility Vehicles

The concept of the sport utility vehicle (SUV) has its roots in the 1930s when Chevrolet designed a vehicle built on a truck frame with an enclosed rear cargo area and marketed it for rough roads and off-road travel. The SUV then evolved over several decades. It was not until the 1980s that the SUV began to gain popularity beyond a niche market, thanks to a combination of new environmental regulations and low gasoline prices.

Sales increased over the next two decades, despite safety concerns and a high-profile lawsuit against Ford/Firestone in 1998. By 2001, SUVs and light trucks accounted for approximately 50 percent of the new car market in the United States. However, higher Corporate Average Fuel Economy (CAFE) standards and soaring gasoline prices allowed crossover utility vehicles (CUVs) to outsell SUVs by 2006, and younger drivers continued to prefer the CUVs.

Although the term *sport utility vehicle* entered the lexicon in the 1960s, automotive historians generally agree that the Willys-Overland, first used as

a military vehicle, was an early predecessor of the SUV. In fact an advertisement in the late 1940s referred to an early civilian Jeep as a "utility vehicle" for the family. The CJ-5, introduced in 1954, is more directly linked to other SUVs, but it was in the 1960s with the introduction of the Ford Bronco, the International Harvester Scout, and the first-generation Chevrolet Blazer that SUVs intruded into the general American consciousness. Even then, they were viewed as specialized vehicles largely limited to forestry agencies, police departments, and sports enthusiasts and other consumers who wanted off-road transport.

In 1965, pickups and SUVs combined claimed only about 20 percent of American passenger vehicle sales. The 1970s saw soaring gas prices and concerns about U.S. dependence on foreign oil, and Congress passed the country's first Corporate Average Fuel Economy (CAFE) standards. The 1975 law called for a doubling of passenger-vehicle efficiency—to 27.5 miles per gallon (mpg)—within 10 years, but gave the National Highway Traffic Safety Administration (NHTSA) the authority to set less rigorous requirements for light trucks.

At the beginning of the 1980s, sales of light trucks (including SUVs) were only around 2 million, but in 1983 and 1984, lighter models of the four-wheel drive SUVs debuted. With the oil crisis past, vehicles such as the Jeep Cherokee, the Chevrolet S-10 Blazer, and, most famously, the Ford Bronco II, which sold to 700,000 customers during the decade, attracted the attention of American consumers. SUV sales increased from 132,000 in 1982 to 800,000 by 1985. By 1987, sales had increased the light truck share of the market to about one-third. The typical SUV owner was a male baby boomer, educated and financially comfortable, and while he may have been attracted to the masculine, outdoors image of the SUV, he used it quite differently than earlier sports enthusiasts. Only 10 percent or so of SUVs of the period were driven off road.

Safety

Not all news about the increasingly popular vehicles was positive. CBS's news magazine, *60 Minutes*, aired footage of the Jeep CJ rolling over while executing a turn during an Insurance Institute of Highway Safety test. By 1983, trial lawyers had learned that Bronco II prototypes were tipping onto two wheels at speeds as low as 20 miles per hour,

This photograph from the U.S. National Highway Traffic Safety Administration shows the 2012 model Ford Explorer, which is now built on a car-based unibody platform instead of its former truck-based platform. Such crossover utility vehicles (CUVs) have claimed over half of the U.S. SUV market in recent years, totaling 23.8 percent of sales by 2012, while SUVs have fallen to only 7.8 percent. Rising gas prices as well as safety concerns about the truck-based SUV models may have contributed to this shift.

a performance that caused Ford to consider and then reject abandoning the Bronco II project during development. In 1986, Congressman Tim Wirth (D-Colorado), concerned about a report that linked the stability of SUVs to the height-to-width ratio of the vehicles, petitioned the NHTSA to mandate changes in the basic design of SUVs. A broad consensus among NHTSA analysts recommended regulation, but NHTSA head Diane Steed, a Ronald Reagan political appointee, denied the Wirth petition. In 2003, NHTSA reported that rollover accidents represented 60 percent of SUV fatalities and 46 percent of serious injuries involving SUVs.

The rollover controversy failed to discourage consumers. The sales of SUVs continued to increase. In 1992, light trucks made up 37.4 percent of all passenger vehicles. The following year Chevrolet and Ford sold more light trucks than cars. Women were buying SUVs in growing numbers during this

decade. They liked riding above other traffic, and they felt they and their families were safer in the larger vehicles. Some analysts have speculated that female SUV owners were also rebelling against the “uncool” image of the soccer mom in her minivan, which had become fodder for the nation’s comics.

In the late 1990s, Ford added the Expedition and Excursion to its lineup, and General Motors added the 4-door Chevy Tahoe and 4-door GMC Yukon. These larger SUVs had larger engines and price tags that were comparable to the mid-size SUVs such as the Explorer, the Cherokee, and the Blazer. Perhaps the large SUVs served as a countersignal to the culture’s demand for downsizing. At any rate, in 1990, 74,000 large SUVs were sold in the United States. By 2009, that number was almost 2.5 million.

Scandal touched the SUV again in February 2000 when a Houston television station broke the news of tread separation problems of Firestone radial

Wilderness ATX tires on Ford Explorers. Later that year, after reports of 33 crashes resulting in 27 injuries and 4 deaths, NHTSA began a formal investigation. Bridgestone/Firestone recalled 6.5 million tires in August 2000, and less than a year later, Ford recalled all 13 million Firestone Wilderness ATX tires that remained on its vehicles.

In November 2000 President Bill Clinton signed the Transportation Reporting Enhancement, Accountability and Documentation Act (known as the TREAD Act), which included early a warning system to detect safety-related defects in automobiles. In October 2001, NHTSA agreed that some Firestone tires tended to separate and required the company to recall an additional 3.5 million cars.

The scandal cost Bridgestone \$1.6 billion in the year after the scandal. Ford's recall cost the company \$3 billion and a brief reduction in market share, but in 2002 the Ford Explorer, widened by two inches and with independent rear suspension, was again America's best-selling SUV, selling ahead of its closest competitor by more than 180,000 vehicles.

Conclusion

By 2005 gas prices exceeded \$3 per gallon, a landmark in American automotive history. Soaring gas prices and economic recession did what safety concerns could not do. The crossover utility vehicle (CUV) was born in 1996 when Toyota introduced its RAV4, which looked like a small SUV but was built on a car chassis rather than a truck chassis. Three years later the Lexus RX, followed by the BMW X5 the next year, revealed the luxury potential of the CUV.

By 2006, when Ford Motors announced that the next Ford Explorer would transition from a truck-based platform to a car-based unibody platform, CUV sales accounted for more than half of the U.S. SUV market. In 2002, crossovers represented 7.7 percent of sales; in 2012, the number rose to 23.8 percent. SUVs, by contrast, claimed about 18 percent of sales in 2002, but fell to about 7.8 percent of sales in 2012.

State Highway Planning and Finance

Considering the vast geographical area of the United States and the strength of its economy, the extent of its highways should not be surprising. According to the U.S. Census, in 2008 there were 4,059,000 miles of roads in the United States. Though the interstates of the National Highway System seem to be everywhere, they in fact make up only about 1 percent of the country's total road network. Local (city, town, county) roads comprise the majority of all roads, but a smaller, though extremely important part of the highway network in the United States, is managed at the state level.

On the most basic level, a state highway is any highway that has been legally designated as such by one of the states. State legislation can make further distinctions, separating state highways from city, town, or county highways. Aside from the fact that simply designating a road as a state highway makes it one, there are definitive aspects that separate them from the federal highways. One factor, however, that is consistently recognized is that state highways exist within the confines of the state borders; they do not cross those borders.

For example, Massachusetts Route 2 crosses the border with New York and becomes New York Route 2, but all Massachusetts control and liability ends at the state line, where it is assumed

by the New York Department of Transportation. State highways do, however, cross municipality or county borders.

Further, state highways are directly funded by revenues allocated by the states, although some funding is received from the federal government. How each state funds its highways is a critical matter, because how money is to be raised in economically difficult times is one of the major responsibilities of the state agencies charged with not only maintaining this infrastructure but also expanding it to fit the needs of the state's economy.

State highways are also not subjected to the same design and construction standards imposed on roads that are part of the interstate highway system. While some state roads were grandfathered into the original National Highway System when it began in the mid-1950s, the federal government's standards for its highways are quite stringent and non-negotiable. These requirements include criteria concerning the number of lanes, width of lanes, width of "breakdown" lanes, banking, grades, the speed that can be sustained, and other factors.

Historically, the funding and management of auto highways has been a state responsibility. States were more active in this field until the National Highway System came into being and states are still very active. Generally, highway funding, planning, policy, safety, and other operations are carried out by each state in a similar fashion.

Every state has some statewide agency that is responsible for its highways. Usually designated as the Department of Transportation (DOT; or transportation cabinet, agency of transportation, or department of roads), this organization may also exercise oversight for other transportation modes, such as air or maritime. In every case there is a highways section that is responsible for all (or nearly all) aspects of managing highways and the resources needed to keep them operating.

At the state level, policies concerning highways are developed and promulgated by the highway department of the state DOT. The standard understanding of what constitutes a policy (regulatory measures, system of laws, funding priorities) applies here but in terms specific to highway operations, funding, and safety. Highway environmental issues such as water runoff and noise are covered as well. Since the advent of the Internet, state DOTs and their subordinate highway departments make these

policies widely available to the general public as well as roadway contractors or transportation advocates to review.

Planning Process

The continued safe and effective operation of state highways relies upon a planning process that takes into account not only finance but also the economic and social needs of the state. In addition, the political realities of the state have an influence. The governor of the state sets his or her priorities, which the Highway Department translates into its plans. The political climate in the state legislature also has an influence. These two sources of influence as well as what experts in the highway agency consider to be the objective needs or desired goals must be combined.

The plans that are eventually published serve several purposes. First they present a long-range statement of what is considered to be the vision for maintaining and improving the highway system. Typically, these plans cover several years, ranging from three years in some states to 20 or 30 years in other states. The published state highway plan not only articulates the vision but also puts it into a form that helps its advocates to sell it to legislators and the public. Behind the formal plan as it is presented is a great deal of work. The plan, in its real form—not only the glossy presentation—must take into account many factors in order to successfully address the technical and logistical details involved.

Highway planning is a classic case of long-range planning that incorporates a large number of stakeholders. Typically, expanding the capacity of already existing highways requires six to eight years, and 10 years of planning is not uncommon for new highway development. Ultimately, the planning process alone will need to consider technical factors of design and construction as well as in-depth studies of the economic and social factors that will affect and be affected by the highway project. Environmental impact assessments must be completed, which explore different alternatives to the basic plan in order to allow planners to select the most environmentally friendly course of action. Environmental studies, once approved, inform the remainder of the development process and are followed by the purchase or other form of acquiring the land needed, if that is the case.

Highway design in both preliminary and then advanced and detailed stages follows. The design of highways is such a technically involved process that in all likelihood no one state can muster the expertise to perform it successfully on its own. There is one resource that exists that enables states to improve existing highways and to develop new highways using the latest advances in design. Every state DOT has joined an organization, the American Association of State Highway and Transportation Officials (AASHTO), which provides expertise derived from experience, design committees, and research. AASHTO is also responsible for the publication and maintenance of standards for the design of highways.

Funding for Construction and Maintenance

After the planning process has been completed, construction can begin. But at the same time that technically realistic and politically feasible planning for highways on the state level takes place, the financial aspects must also be studied and resolved. Financing highway development and maintenance has become perhaps the most complex issue facing all state highway departments and DOTs.

The economic situation in the United States in the past decade has presented challenges to financing highway work. Even with the economic downturn and other factors that make collecting revenue more difficult, highways and roads still deteriorate. Despite a slowing economy, consideration must still be given to expanding highways in order to provide the type of infrastructure that cities need today and for the future.

Fuel taxes have always been a means of collecting revenue for federal and state highway funding (local roads are usually financed by property, sales, and other taxes). In the first decade of the 21st century, fuel taxes accounted for approximately one-third of state highway revenue.

Although gas taxes have existed since 1932, in the past 20 years, they have not been as dependable or as significant a source of revenue as they once were. There are several reasons for this. Better gas mileage in vehicles (which decreases the number of gallons purchased) has been a major factor. Another aspect to this problem is that gas taxes have not kept pace proportionally with the increase in the price per gallon. In addition, the revenue raised through taxes on fuel has not kept pace with the increases in labor

A New York State Thruway sign below the Interstate 87 shield in Ramapo, New York. State highways like the New York State Thruway are directly funded by revenues allocated by the state, although some funding is received from the federal government.

and materials costs associated with highway repair and construction. Finally, purchases of trucks to haul freight on the highways have declined, further eroding a source of additional traffic and income.

Had fuel taxes been raised as frequently and in proportion to increases in the price of gasoline, they would be several times their current rate. This is generally true for the states just as it has been at the national level, where no raises in the federal fuel tax have been made since 1997 (as of 2013). In the past, as is the case with any tax, fuel taxes have been increased with relatively little opposition.

One reason for the lack of significant opposition was the fact that the tax revenue went directly to roadway maintenance and improvements, which benefited all users. In the current political atmosphere, however, raising taxes of any kind, even

those that not particularly unpopular, is increasingly difficult.

One alternative to fuel taxes that has been discussed is a charge based on vehicle miles traveled (VMT). One argument in favor of this kind of tax is that it puts the burden of payment on users in proportion to their actual road use. Others argue that this would be bad policy as it would penalize those who purchase fuel-efficient vehicles. There have also been privacy objections raised, as collecting the tax would require acquiring data on individual automobile use. Fortunately for state highway finances and planning, there are other sources of income. These include tolls (and their increasingly creative application), other user-related fees (such as registration and license fees), and federal aid in the form of regular grants and those received from the American Recovery and Reinvestment Act (ARRA) of 2009.

Toll Roads

Toll roads are a fact of life in the United States and have been since the 19th century, when the construction of new roads was financed by levying tolls on traffic. In the 20th century, making a road a toll road was a common practice, as it still is. In states such as Florida, New Jersey, New York, Pennsylvania, and Illinois, road tolls account for at least 10 percent of their total highway revenue.

In some instances in the past, the tolls were removed when the highway was paid for. In other instances, the tolls have remained in place for decades to continue financing highway maintenance. In some instances, tolls are being reinstated on roads. In some locales, such as Texas, newly opened roads are now routinely starting their existence as toll roads. While that approach can be expected on the basis of paying for new construction, it also can be seen as a reflection of the current political situation, where there is less willingness for a political entity to require all of its citizens to pay for something (through fuel taxes) that benefits one region. In this way, the expectation is that those who benefit directly will pay directly for construction and, presumably, for upkeep.

There have also been two variants on the use of highway tolls. Private funding for the construction of new roads in some instances has been implemented. In these cases, the private financial entity finances the roads and in return receives an agreed-upon percentage of tolls for a specified time period.

Another means of using tolls has been to charge variable tolls for the use of certain routes at specified times of day. Routes that are not as congested during rush hour traffic are now sometimes charging an increased toll rate. The idea is that if a driver wants to cut commuting time and uses a particular route to do so, he or she must pay an additional amount. This last solution has been tried but has not reached wide use.

Other Revenue Sources

In all cases described above, the revenues come to the state as a result of payments in one form or another by users. According to the Federal Highway Administration, however, there has been a decrease not only in fuel taxes as a source of income but all of these user-related fees are bringing in less income than before. At the end of the first decade of the 21st century, this user revenue amounts to only half of the funding used for highway construction and maintenance.

For that reason, assistance from special programs (such as issuing bonds by states) is required. The main source of revenue for the remaining 50 percent of needed funding is federal aid. One direct source of aid as well as a source of management, risk, and safety advice to the states is the Federal Highway Administration (FHWA). Coming into existence in 1966 as part of the U.S. Department of Transportation (USDOT), it oversees the federal funds disbursed to the states for maintenance and construction of state highways as well as activities on the National Highway System.

In addition to its long-time oversight responsibilities, the FHWA exercises the same function over part of the funds available through ARRA grants. Of the total American Recovery and Reinvestment program, \$48.1 billion is allocated to the Transportation Income Generating Economic Recovery (TIGER) Grants. Of that, over 50 percent is to be distributed to the states for highway and bridge construction. Thus, even for state highways, there is a significant amount of funding that comes from the federal government.

State Implementation Plans

A state implementation plan (SIP) refers to a collection of reports that details a specific program of forward-looking environmental initiatives, policies, and rules established by states, territories, and the District of Columbia. Local and state agencies are obliged to file the SIPs with the U.S. Environmental Protection Agency (EPA) to indicate their intention to implement specific measures to attain and maintain the National Ambient Air Quality Standards (NAAQS) for primary- and secondary-criteria pollutants. The measures pay particular attention to bringing predesignated polluted zones (nonattainment areas) under their jurisdiction into compliance with federal standards for clean air.

The SIP is a way to compel both local and state authorities to move decisively and pragmatically to respond to pollution alarms before the air quality has been too thoroughly compromised. SIPs, then, provide the mechanism for speedy and directed response to air pollution concerns. The SIP itself is an often massive document filed with the EPA and available for public inspection (indeed, most states maintain a Web site specifically to detail such compliance initiatives as a way to promote an environmentally friendly spirit and help attract

both new residents and new businesses). The SIP is a broad, comprehensive document with four necessary parts: the narrative, which stakes out the dimensions of the problem and provides critical statistical data on air quality matched against federal standards; the rules, which outline the specific programs for addressing that pollution; the technical documentation, which provides the scientific backup for the proposed programs and verifies that the programs are not only doable but also practical, with specific and immediate benefits; and the legal agreements, which provide mandatory documentation signed by local and state officials as well as the state EPA representative.

It would be a misperception, however, to assume that despite such mandatory elements and tidy divisions the typical SIP is an actual report stored in some computer file or handed around in a three-ring binder in the EPA offices in Washington. In fact, seldom do the filed documents actually include specific plans for addressing the affected areas—rather, the SIP documentation demonstrates that the state understands the problem and its dimension and that it has every intention to pursue means to effect the maintenance, restoration, enhancement, or protection of its nonattainment zones.

A typical SIP can run to hundreds of pages in the state's efforts to provide a sufficient record of public and industry responses, measurements of pollutants, listings of federal regulations, environmental emission models, and data sets on non-compliant areas. Each initial SIP covers a five-year period in which the state identifies how it plans to achieve any pollution reductions to meet the federal clean air standards. Updates are required every three years thereafter to ensure continued compliance.

It is up to local and state authorities to develop specific programs or to implement new policy guidelines to achieve the designated numerical standards, with the EPA monitoring their progress. In this way, the SIP represents a bold initiative in federal and state cooperation, a partnership among local, state, and federal departments as well as the general public.

As a first step in filing an SIP, state and local environmental agencies enter monitored air quality data into a mathematical model that in turn matches the data against the federally mandated numbers and comes up with a kind of baseline figure that measures the range of compliance. As with any

calculations that involve the environment, however, the numbers are never simple.

Indeed the model used by the EPA in connection with the SIP program is quite complex. The determination of nonattainment status, after all, needs to factor in a wide range of variables: average wind speeds, tree and brush growth, traffic patterns, atmospheric chemistry, water resources, highway system integrity, demographics and population distribution, and recurrent weather patterns. Once the data indicates a problem, the process enters its second stage as local agencies begin to consider possible solutions.

At a time of increasing conflict between the federal and state governments, SIPs have evolved in an environment of cooperation and shared responsibility. But the expectation is clear: quantifiable results that are sustainable, enforceable, and permanent. The overall purpose served by an SIP, then, is actually twofold: (1) to reassure federal environmental watchdogs that the state has, in fact, a strategic initiative in place to monitor and control air pollution; and (2) to indicate the specific federal emissions control requirements that will guide whatever initiatives the state will undertake.

Each SIP must be signed by local and state authorities and approved by the EPA. The EPA, in turn, monitors the progress in cleaning up any nonattainment zones—failure to comply within a reasonable time frame provides the EPA the authority to levy fines to compel compliance, withhold federal project dollars, and, in extreme cases, pursue criminal action.

The authority for the federal government to act as watchdog of the nation's air quality dates to concerns first raised immediately after World War II about air quality in the Northeast Corridor. But specific actions to monitor air quality were begun with the federal Clean Air Act of 1963 (CAA), a part of the John F. Kennedy administration's bold (and groundbreaking) environmental policy initiative.

By contemporary standards, of course, the initial version of the CAA seems soft and inexact—providing little more than incentives for local and state governments to become aware of the increasing volume of air pollution in cities and its effect on public health while funding programs designed to devise possible strategies for cleaning up the air. The thin authority structure and vague criteria used in that initial law gave the program little chance for significant success.

When the federal act was revisited for its renewal in 1970, legislators, acting on the counsel of blue-ribbon committees of environmental scientists now alarmed over the unchecked spread of unhealthy air, passed a far stricter bill that actually provided ranges for acceptable and unacceptable levels of air pollutant emissions. Within the year, the EPA was established and put in charge of monitoring compliance nationwide, recognizing that any success in containing and controlling air pollution had to be decentralized, as state-to-state air quality was shared but appropriate attention to controlling it was not.

In addition, the EPA recognized that, unlike the wider and more open spaces of the west (save California), the Midwest states and, particularly, the Northeast basically shared the same "airshed"; thus, providing standards for clean air was a federal rather than a state concern. Under the provisions of this version, the EPA was given specific authority to actually limit emissions from such traditionally heavy polluters like factories, mills, and utilities. This provided the federal government with unprecedented responsibilities for environmental advocacy.

Over the next decade, as the EPA became embroiled in a number of very public scandals involving the illegal distribution of cleanup monies, new concerns were voiced over the sprawling (and often unchecked) authority the administration had been given. When the bill was renewed again in 1990, recognizing the size of the investment necessary to address the nation's air quality, provisions encouraged cost-effective protocols for reducing air pollution, requesting states target small-range projects to attain goals over a period of time rather than sweeping changes that could negatively affect state budgets. And during the Bill Clinton administration, with its emphasis on business-friendly environmental policy that encouraged practical and specific goals, the EPA moved to make air quality control manageable with results that were both real and measureable.

The SIP, as an instrument of compliance intentions, provided exactly that. Using its broad authority, the EPA designated six specific, common pollutants to measure for compliance, pollutants known to cause damage to property and the environment and also to cause long-term health problems. The six are ground-level ozone (smog), particulate matter

(a kind of pollution soup, often described as haze, comprised of liquid droplets and a variety of coarse inhalable particles—more than 10 micrometers in diameter or smaller and including particle acids, carbon-based chemicals, metals, common dirt, and even dust), lead, carbon monoxide, nitrogen dioxide; and sulfur dioxide. These are designated as criteria pollutants because the EPA sought to control them by providing specific (and stringent) criteria for acceptable and unacceptable levels. By designating specific pollutants, the EPA provided the frame for state by state compliance.

The SIP forecasts levels of pollutant emissions that will achieve the NAAQS (the “emissions budget”) and identifies pollution control strategies that will enable steady progress toward attainment of these air quality standards by the applicable deadlines set by the CAA. The SIP reassures the federal government that all states have both the capacity and the specific initiatives to meet those standards.

When an area, most often a metropolitan area or an area of significant industrial development, fails to attain the compliance level for one or more criteria pollutants, local authorities, along with business and industry representatives, stake out specific short-term projects that will reduce the level of those pollutants in the designated area.

In addition, the SIP must provide long-term strategies for continuing to ensure air quality is maintained at acceptable levels. Importantly, under the federal CAA, transportation activities that receive federal funding or approval must be fully consistent with the SIP. These include the 20-year regional transportation plan (RTP), or a short-term transportation improvement program (TIP), which if implemented must not result in emissions that exceed the SIP’s emissions budget. Additional transportation control measures (TCMs) may be required if needed to reduce vehicle emissions due to traffic congestion or growth in the overall number of vehicle trips and/or travel miles.

Of course, the EPA, with its broad authority, can reject an SIP and create its own strategy for compliance (a document known as a Federal Implementation Plan, or FIP); but such actions are rare. The reality of managing state resources and reallocating public monies to address air quality requires extensive familiarity with local political structures, regional industrial bases, particular geographic features, housing patterns, population dispersal, and

economic factors; thus, the EPA generally leaves specific compliance strategies to the local levels.

SIPs are a matter of public record and are readily available for review on state Web sites. Of course, public advocacy groups pushing for more stringent standards in the face of growing concerns over climate change may find much in SIPs to disparage. However, the SIPs have been largely lauded for pressuring local governments to maintain air quality for the common good. Although the SIPs themselves are not required to itemize specific programs designed to bring air quality into alignment with federal standards, the range of programs initiated as a result of SIPs is not only impressive but represents the innovative, resourceful, and technological creativity of state and local governments when they are directed to resolve a particular pressing problem.

Measures taken to improve ambient air quality in reaction to SIP reviews can include broad, regional programs with massive price tags or relatively modest programs that nevertheless achieve significant results. SIPs have been responsible for improvements to public transit systems; traffic flow redesign to minimize starting, stopping, and idling, all heavy contributors to emission levels; bans on open burning; the construction of serviceable bicycle paths and pedestrian walkways; programs designed to encourage flexible work schedules to decrease rush hour traffic; the construction of high occupancy vehicle (HOV) lanes to encourage carpooling; upgrading industrial and plant equipment to reduce emissions; redesigning traffic flows by constructing multilane off-ramps; and funding private enterprise and university research teams to improve emissions equipment on all vehicles, particularly those more than 10 years old.

There have been problems. Despite the much touted federal–state partnership, limits to federal funding and support make the SIP a resource-intensive operation for local and state governments. The process itself is heavily bureaucratic involving accumulated (and redundant) paperwork. The process of filing the SIP is complicated and time-consuming. But perhaps the most directed criticism of the SIP process is that it compels states to focus on generating figures demonstrating attainment in the plan rather than tracking the methods for achieving those numbers. But on the whole the SIP program has worked—levels of criteria pollutants have

consistently been dropping since 2000, and air quality in major cities is quantifiably cleaner.

State Transportation Planning

Each state as well as Puerto Rico and the District of Columbia has an agency or department officially charged with the responsibility of transportation planning, generally designated as the Department of Transportation (DOT). Typically, these departments not only have responsibilities for the planning, operation, and maintenance of multiple modes of transportation (air, water, and surface) but they also must work cooperatively with other agencies involved with transportation.

Since Congress passed the Federal-Aid Highway Act of 1962 and tied federal funding of surface transportation to meeting certain requirements, states, through their departments of transportation, have also been charged with ensuring that statewide transportation planning conforms to federal regulations.

The organization of the departments of transportation and the policies through which the state allocates responsibility, manages personnel, and establishes procedures and practices to perform tasks associated with the planning process vary from state to state, but all state DOTs are involved in activities such as managing transportation planning, coordinating projects among various agencies, involving the public in procedures for transportation planning, and working on intermodal planning and congestion management.

The transportation planning process of each state must address both urban areas and areas outside metropolitan areas. Since the 1970s, states have had to coordinate planning for urbanized areas with metropolitan planning organizations (MPOs), organizations in urbanized areas with a population of 50,000 or more that are mandated and funded by the federal government. Any urban transportation project that receives federal funds must come from the appropriate MPO and the state transportation planning process. For projects in areas not covered by an MPO, states must provide opportunities for local officials to participate in the planning process. Some states meet this requirement through rural planning organizations, typically voluntary organizations through which local officials arrive at consensus on regional transportation priorities.

In 2012, federal law authorized the creation of the Rural Transportation Planning Organization (RTPO). The change gives such groups greater status, although the choice to create an RTPO still rests with each state. Some already existing rural planning organizations serve multiple rural counties with combined populations exceeding the minimum 50,000 of an MPO.

Long-Range State Transportation Plan

In order to receive federal funding, states are required to develop a long-range statewide transportation plan that identifies a state's direction for its transportation investments for a period of at least 20 years. Within this general requirement, the plan

may vary widely in content and approach. Some states develop a needs-based plan. They consider the existing transportation system and identify current and future needs based on demographic and transportation trends and projections. Others prefer vision-based plans that focus on an ideal image of what the state's future transportation system should be. Still others are policy based, describing strategies that will be used to achieve goals and official public policies for solving problems and meeting demands.

Project-based plans offer another option. States choosing this approach identify specific projects to meet identified needs and may even include projected costs. Other states have corridor plans that consider specific transportation corridors and their needs. The best of these plans include all transportation modes and refer to both passenger and freight needs. A final category is the fiscally realistic plan that sets the state's long-term direction with due consideration of projected capital, operating costs, and revenue sources. Some states may combine two or more of these approaches.

Regardless of differences, each plan must include information on the development and implementation of a multimodal transportation system for all areas of the state and provide for public comment before the plan is published. Legislative changes in 2012 added the requirements that the long-range plans of the states must include a description of the performance measures and targets used in assessing system performance as well as a system performance report and subsequent updates evaluating the condition and performance of the transportation system in relation to the performance targets.

Unlike MPO plans, which must be updated every four or five years and are required to identify project costs and revenue sources, the long-range transportation plans of the states are required to be updated only as needed and are not required to include specific projects or to explain fiscal constraints if projects are included. However, state DOTs must have a documented process for consulting with officials in nonurban areas and with officials of Native American tribes. Although states are required to provide copies of their long-range transportation plans to the Federal Highway Administration and the Federal Transit Administration, the plan does not require the approval of any federal agency.

State Transportation Improvement Program

Each state must also develop a state transportation improvement program (STIP). This document covers at least a four-year period of the state's program of transportation projects that are to be financed by federal surface transportation funds. The STIP also includes regionally significant projects that require action by the Federal Highway Administration or the Federal Transit Administration, whether or not the projects are federally funded. Each project included must be consistent with the state's long-range transportation plan as well as with any relevant long-range metropolitan transportation plans. Fiscal constraints are also in effect for all projects. The state is allowed to include only projects or project phases for which full funding can be reasonably anticipated within the specified time frame of the project.

Each MPO in the state is required to have a transportation improvement program for federally funded projects for the next four years. Federal law requires that each MPO transportation improvement plan, or TIP, be included without change in the state transportation improvement program, directly or by reference. Additionally, MPOs serving urban areas with a population in excess of 200,000 are required to have a congestion management process that specifies congestion-reducing actions and strategies. Most states include state-funded projects in their plans as well, but all federally funded projects must be included in the STIP before the Federal Highway Administration or Federal Transit Administration can authorize the expenditure of federal funds.

When the state submits the STIP to the Federal Highway Administration and the Federal Transit Administration for review and approval, each agency reviews the plan, and they jointly declare the extent to which the STIP is based on a process that meets or substantially meets the federal planning requirements that include but are not limited to the demonstration of fiscal constraints, the use of a documented process for involving the public and consulting with officials outside MPO areas, and including MPO transportation improvement programs in the STIP.

New Projects and Federal Funds

Congress established the Office of Road Inquiry in 1896 and passed the first Federal-Aid Road Act in 1916. That act created the Federal-Aid Highway Program through which funds were made available to state highway agencies to help improve

roads. By the 1920s, the Office of Road Inquiry had become the Bureau of Public Roads, and the Federal Highway Act of 1921 authorized the newly named agency to channel funds to the states to help in the construction of a paved system of two-lane interstate highways. When the Great Depression of the 1930s struck, the Bureau of Public Roads assisted state governments in creating road projects that gave jobs to thousands of the unemployed.

World War II turned the focus to roads needed for defense, and President Franklin Roosevelt signed legislation in 1944 authorizing a network of rural and urban express highways called the National System of Interstate Highways. The Bureau of Public Roads, which had been renamed the Public Roads Administration (PRA), implemented Section 7 of the law, asking the states to submit recommendations for routes to be included in 40,000 miles of the new interstate system. The PRA also worked with state and local officials to make interstate plans for larger cities.

The 1950s saw the beginning of what was called the “greatest public works project in history.” The Federal-Aid Highway Act of 1956 expanded the interstate system to 41,000 miles and authorized \$25 billion for fiscal years 1957 through 1969. Highway construction employed tens of thousands of workers and eventually helped the interstate trucking industry surpass railroads to gain the dominant share of the domestic shipping market. Fast food chains, hotels, and amusement parks proliferated, and a decade later America had become a nation of drivers. The Highway Revenue Act, also passed in 1956, created the Highway Trust Fund and provided that revenues from certain highway-user taxes would be credited to the fund to finance the expanded highway program enacted in the Federal-Aid Highway Act of 1956. Ninety percent of the highway costs were covered by federal appropriations, and 10 percent by the states, which were also responsible for awarding the construction contracts and managing day-to-day maintenance operations and law enforcement.

The 1960s brought the Federal-Aid Highway Act of 1962, an act that authorized federal highway funding for fiscal years 1992 through 1997 and for the first time linked federal funding to conformity to specific requirements, forever changing the roles of the federal government and the states in the area of transportation funding. The new law also made

the four-cent gas tax permanent and adjusted other excise taxes. It adjusted remaining authorizations for the system to a total of \$25.2 billion over nine years. With the states’ matching funds, the legislation accounted for \$27 billion in funding for the remainder of the program through fiscal year 1971, the same amount Congress had thought in 1956 would be the total cost of the program. Four years later, the Department of Transportation was officially established, with the Bureau of Public Roads undergoing a name change to the Federal Highway Administration as one of its divisions. Throughout the 1970s and 1980s, the Federal Highway Administration worked with the states to open 99 percent of the designated 42,800-mile interstate system—officially called the Dwight D. Eisenhower National System of Interstate and Defense Highways.

ISTEA and the Next Revolution

The Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA) moved transportation regulations and funding into the post-interstate era. The \$155 billion act revolutionized transportation planning and the relationship between the federal government and the states. ISTEA stressed intermodalism—the connections among highway, rail, air, and marine transportation. The statute also gave state governments greater flexibility in finding solutions to their problems. Federal funds could be used for projects that alleviated traffic congestion, increased safety, and improved air quality. With four decades of interstate highway system construction in the past, ISTEA emphasized maintenance rather than expansion. It established an Interstate Maintenance Program for resurfacing, restoring, and rehabilitating the interstate highway system.

One of the most significant changes was the Surface Transportation Program (STP), which did not limit federal highway funds to highways and transit projects but allowed states to use federal dollars for a range of projects that supported the intermodal concept, including bridges on public roads, transit capital projects, carpooling projects, safety improvements, bicycle and pedestrian facilities, and transportation control measures. Another intermodal initiative, the Congestion Mitigation and Air Quality Improvement Program, enabled states to direct federal dollars toward innovative projects that did such things as establish rideshare services, promote employer trip-reduction programs, and

support bicycle and pedestrian travel—all with the goal of improving air quality and reducing traffic congestion. At first, use of these funds was limited to projects in areas that failed to meet national air quality standards set by the Clean Air Act, but later changes in the law allowed the funds to be used to maintain air quality in areas that were in compliance with federal standards.

One of the most popular features of ISTEA with the public was the Transportation Enhancement Program, which supported construction of pedestrian and bicycle facilities, acquisition of scenic and historic sites, rehabilitation of historic transportation facilities, archaeological planning and research, control and removal of outdoor advertising, and mitigation of water quality effects from roadway runoffs.

In 1998, the Transportation Equity Act of the 21st Century (TEA-21) became the successor to ISTEA. TEA-21 authorized more than \$200 billion to improve transportation infrastructure, enhance economic growth, and protect the environment. New regulations emphasized environmental concerns particularly. Ten percent of Surface Transportation Program (STP) funds (\$3.3 billion over six years) was set aside for transportation enhancements, including a wide range of environmental and water quality improvement projects such as pollution abatement and mitigation projects.

TEA-21 also allowed as much as 20 percent of the cost of a transportation facility reconstruction, rehabilitation, resurfacing, or restoration project under the STP to be used for environmental mitigation, pollution abatement, or construction of storm water treatment systems. Also, states were allowed to use STP and National Highway System funds for wetlands projects designed to offset impacts from past transportation projects. The federal share for some TEA-21 and restoration projects, depending upon program requirements, was 80 percent.

TEA-21 also offered a new planning tool: guaranteed funding. For the first time, protections prevented spending for highways, highway safety, and transit from being reduced to increase spending for other discretionary budget programs. Guaranteed amounts for highway spending were linked to actual Highway Trust Fund receipts, and only projects eligible under federal highway and highway safety programs could be supported by these funds. Guaranteed funding gave states the ability to plan

transportation programs with a reasonable expectation of having the funds to finance them.

In 2005, the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU), as the acronym suggests, targeted safety concerns, nearly doubling funds for infrastructure safety and including programs that focused specifically on concerns such as work zones, older drivers, and pedestrians, including children walking to school. Building on TEA-21's guaranteed funding, SAFETEA-LU included an Equity Bonus program that ensured that each state's return on its share of contributions to the Highway Trust Fund (in the form of gas and other highway taxes) was at least 90.5 percent in 2005 and reached a minimum 92 percent relative rate of return by 2008. Every state was also ensured a specified rate of growth over its average annual TEA-21 funding level, regardless of its trust fund contributions.

Among SAFETEA-LU's most substantial provisions was the retention of TEA-21's environmental programs with increased funding. The law added new environmental programs, including a \$100 million pilot program for nonmotorized transportation. The funds were divided equally among four communities: Columbia, Missouri; Marin County, California; Minneapolis–St. Paul, Minnesota; and Sheboygan County, Wisconsin. The goal of this 100 percent reimbursement project was to construct a network of nonmotorized transportation infrastructure facilities (including sidewalks, bicycle lanes, and shared-use paths that connect directly to transit stations, schools, residences, businesses, recreation areas, and other activity centers) to demonstrate a mode shift from motorized travel to bicycling and walking transportation.

Delayed Action and Questions for the Future

After a series of extensions and a delay of more than three months after the expiration of the previous law, Congress passed the Moving Ahead for Progress in the 21st Century Act (MAP-21) in summer 2012. The legislation consolidated or eliminated more than 70 federal programs. It also required states, localities, and transit agencies to establish performance targets and incorporate them into their transportation plans and project selection, and made major reforms and improvements to the project delivery process.

This reform brings welcome relief to states that often must wait several years, sometimes as long as 14 years, to complete projects that require federal funding. Other changes include the Cardin-Cochran provision that provides grants to local communities to make their streets safer for walking or biking, although at a lower amount than supporters hoped. About half the money is designated for metropolitan areas, with the remainder used at state discretion. MAP-21 also created a new program that provides relief for public transportation systems that are affected by a natural disaster or catastrophic failure. This program has already been utilized by the states and transit agencies impacted by Hurricane Sandy.

MAP-21 is set to expire on September 30, 2014. Politicians and pundits predict that the Highway Trust Fund from which the federal share of transportation programs is funded almost entirely will be insolvent starting in fiscal year 2015. By the end of 2014, a total of \$54 billion will have been transferred from the General Fund into the Highway Trust Fund to maintain its solvency. This includes an \$18.8 billion transfer authorized by Congress in MAP-21.

On average, states depend on federal funds for half their annual capital spending on bridges and highways. Some states rely even more heavily than the average. Federal dollars fund more than 70 percent of transportation spending in 10 states, and in the two states with the lowest gasoline taxes in the nation, the amount is considerably higher: 79 percent in South Carolina and 93 percent in Alaska. States have responded to their precarious position in a variety of ways. Some have raised state gas taxes, some have replaced gas taxes with sales taxes, and some have sought private-sector financing. Others are experimenting with toll roads or fees based on miles driven. Meanwhile, lawmakers continue their partisan battle on the issue of higher gas taxes, and state transportation planning faces an uncertain future.

Street Design/Patterns

Street designs evolved rapidly during the late 19th and all of the 20th century because of the invention of the combustion engine and the development of the private motor car. As more people became car owners, cities expanded to meet the desire of people to live further away from city centers in suburban areas where open space was plentiful and travel was easy. As the 20th century continued, different forms of street patterns were designed and built to accommodate the rapid growth of cities. However, this led to conflict between motor users and pedestrians as roads became barriers to walkability.

Street designs in most cities around the world are often the result of three different types of interactions: the main form of transport in use at the time of the city's formation, the various planning policies over the years, and the growth that the cities may have experienced during their existence.

Street designs, however, are also conducive to the quality and social interaction that takes place within any community, linking different parts of neighborhoods and providing access to all parts.

Origins of the Grid Layout

For long periods of time in Europe, most cities followed the “gridiron,” or grid, layout of roads made popular by the Roman Empire 2,000 years ago. This involved a series of roads running parallel with another series of parallel roads intersecting with them at 90 degrees. This layout, originally intended for the ease of walking and simple in its design and simplicity, was repeated throughout the Americas when European settlers arrived in the 17th century.

In America, the grid layout was adapted to take account of the vast open spaces and tracts of land that the pioneers encountered. The Northwest Ordinances carried out in 1785 and 1787 established the pattern for the grid for American cities. This created six-mile squares across the continent, leaving these squares simple to survey, easy to divide, and establishing everything at right angles.

Apart from a few exceptions, this method of street design was accepted as the easiest method of planning and design. This allowed for its “blocks” to be easily surveyed and recorded for ease of ownership, as well as ease of pedestrian movement around the city. It was not until the advent of the combustion engine and the motor car that the grid system of street layouts slowly began to change.

The advent of public transport—before the motor car came into existence—allowed workers (commuters) to live farther away from their workplace and provided efficient longer-distance commuting. This led to suburbs springing up on the edges of cities that once again used grid patterns but sometimes incorporated diagonal streets, making pedestrian access to public transport accessible. As the passenger numbers increased, the main stops and terminals became social and commercial centers, shaping the future layout and planning of these areas.

Advent of the Automobile

It was the introduction of the motor car, and the ability of the middle and working classes to purchase one, that led city planners to be released from the constraints of having to plan mainly for the pedestrian. The grid pattern was the mainstay of most city road layouts until the growth of people owning their own vehicles caused a series of gridlocks in many populated cities.

As suburbs rapidly grew and expanded in cities around the world in the 1920s and 1930s and as the number of motor vehicles grew from 2 million in 1915 to almost 10 million by 1920 in the United States, planners were being driven by the demands of the motor car rather than pedestrian movement and public transport. Indeed, it is only nearly a century later that the problems caused by the motor car in the development of the cities are finally being addressed.

The motor car revolutionized the way suburban street design developed. With everything in and around the city within easy reach, the traditional planning of a city made on the premise that most things had to be within walking distance was swept away and planning based on the car took precedence, mainly involving an increase in the traveling speed. However, with the car literally driving the direction of these new suburban areas, it brought with it its own disadvantages. Suddenly, planners had to deal with the effects the car brought: pedestrian dangers, noise, and exhaust fumes.

Planners, as they are known today, did not exist at this time. Traffic engineering was not even recognized as a separate engineering discipline. Road designers, as such, worked in an emerging field of knowledge that was acquired through actual application. Only a small number of engineers understood the fundamental differences between transport planning and road construction techniques, a legacy with which many cities have had to deal during recent times. Many of these early road engineers were civil or electrical engineers self-taught in the areas of transportation planning and construction.

The U.S. Institute of Transportation Engineers (ITE) was formed in 1930, and a specialized program at Yale University was established with the aim of

. . . study and improvement of the traffic performance of road network and terminals. Its

purpose [was] to achieve efficient, free, and rapid flow of traffic . . . based on scientific and engineering disciplines.

The early papers and publications that emanated from ITE set the tone of road engineering and transportation planning from the 1940s onward, featuring efficient high-speed road networks over local residential networks.

The evolution of street patterns since 1900 shows the influence the car has had on determining the planning policies that inevitably followed. Rather than planners being proactive in accommodating the growth of motor vehicle owners, they became reactive. The demands of people wanting to live farther away from the city centers and commute into them became the defining element in the way cities expanded and grew, helped along by the inexpensive cost of gasoline.

New Designs

In the 1920s, Raymond Unwin, Thomas Adams, and Clarence Perry—the first of the suburban designers—tried to end the dominance of the grid pattern by arguing that localities should protect neighborhood living through planning measures. Some of these guiding principles were the adaptation of streets to the traffic load and type of use they would have; widths of streets being determined on their hierarchical status; landscape circles or ovals interposed at junctions to compel cautious driving; staggered cross-streets and cul-de-sacs contributing to safety, attractiveness, and variety; and, if long blocks were used, pedestrian footpaths offering shortcuts.

Radburn, New Jersey, was the first suburb to adopt these principles on the basis that the residential neighborhood as a unique identity needed to be protected and deliberately planned. Although innovative and widely accepted as a template for all suburban design, the concept was not taken onboard by the private sector. The chief obstacles to the broader acceptance of the concept were the prevailing small-scale building enterprises and the lack of comprehensive planning policies capable of implementing the concept.

Superblocks brought a new method of traffic circulation into play. Traffic would travel along wide collector roads or divided arterials with landscaped areas in the center, while people walked along

landscaped footpaths, evoking the rural setting and foot accessibility of the pre-automobile era.

As cities expanded beyond the central grid pattern either in a square or rectangular grid layout, the 1950s saw the introduction of fragmented parallel-grid patterns. These allowed for longer street lengths, which in turn led to more green spaces in terms of parks and open spaces.

As the car became ever more popular, the following decade saw a slight variation to the fragmented parallel grid pattern in the form of the warped parallel grid pattern. This allowed for a curvilinear type of road running parallel with another, offering a more pleasing aspect to traveling and breaking the typical grid pattern that existed up until then.

Loop and Cul-de-Sac Layouts

With the ever increasing influence of the motor car, adaptations to the parallel grid-pattern layout evolved. This resulted in the introduction of looped roads and cul-de-sacs for housing away from the main roads, the elimination of footpaths and park land, and more intense commercial development at the sacrifice of the overall aesthetic and pleasantness of the original model.

Developers of residential subdivisions soon preferred loops and lollipops, as well as cul-de-sac street types, rather than the parallel-grid pattern type. Although all three types are efficient in terms of traffic movement, comparable residential densities for the loop and cul-de-sac street types were more efficient in comparison to the traditional grid pattern.

This also meant more land could be built on. The fringes of the city became a series of sprawling suburbs as the rise of the motor car continued unabated in the 1970s. A by-product of the increasing areas of suburbia was the construction of freeways from the most popular areas to the city center.

With the cost of living closer to the center of a city rising year by year, the expansion into the suburbs continued unabated into the 1980s. Great swaths of land were acquired by developers and similar-looking housing estates sprang up. These estates had a sprawling street pattern that promoted a feeling of privacy with short streets in disconnected subdivisions, the “lollipop on a stick” layout.

However, this marked a turning point in the way the car had led the expansion of city planning and development. Public transport facilities had been

stretched, rather than expanded, to cope with the growth of cities and offered no viable alternative to the convenience of the car. This in turn led to the capacity of the main collector and arterial roads becoming stretched to the point where traffic congestion traveling in and out of cities during rush hour (and at other times in some cities) was a daily occurrence.

The loop and cul-de-sac street layouts evolved because of the motor car rather than as a logical planning step for all forms of transport. While cities underwent expansion during the 20th century, the availability of land, the low cost of fuel, and the local authorities' willingness to provide roads (often in conjunction with the developers) fed the expansion boom. The invention of freeways compounded the boom.

It was not until the problems of traffic congestion became commonplace that attitudes changed. Once planners and local authorities realized that if a new road or freeway were built to alleviate congestion, sooner or later these new roads would too become congested, and they began to look at ways of trying to reduce car use by financial means—parking charges, congestion charges, etc.—and encouraging people to use public transport once more.

The original gridiron layout that still existed in the center of the cities was now shown to be an inefficient carrier of motor vehicle traffic. With grid intersections offering 16 points of conflict, each intersection became a barrier to free-flowing traffic. The introduction of traffic lights brought some order to the traffic flow but introduced idling time for vehicles. This, of course, led to an increase in pollution, with traffic exhaust fumes being pumped into the streets.

These grid intersections often occurred every 200 to 250 feet (65 to 80 meters) or 7 to 9 seconds at typical car speeds, which created an obstacle to the motor car's main aim to provide a rapid form of transport. The grid, for so long the mainstay of city centers, had become an impediment to car traffic, compromising speed or safety or both. When large amounts of traffic were present, even with the introduction of traffic lights and stop signs, the end result would be gridlock.

This does not mean that the later adaptations of street patterns, most notably the loops, lollipops, and cul-de-sac patterns, were congestion free. Congestion occurs on arterial roads in the above

A loop and cul-de-sac street layout seen from above in a housing development in Las Vegas, Nevada, in 2000. Developers appreciated the residential densities allowed by such designs, but they have tended to inhibit pedestrian travel.

patterns, not by any fault of the road network, but by the segregation and concentration of similar land uses, such as shopping malls, retail parks, or office parks.

Because these patterns have been designed specifically for the car, they are not suited for pedestrian use. While cities grew to accommodate the need for more housing, and roads were built to increase the frequency of people traveling in their cars, thoughts of pedestrian usage—which was a main driver of the grid system—were very rarely entertained. The discontinuity of the loops, lollipops, and cul-de-sacs inhibit pedestrian access to the facilities and amenities easily reachable by motor vehicles, while their curviness lengthens and deters walking trips.

Street Quality Components

The quality of streets depends on both physical and operational components. These components produce an image in the pedestrian's mind of sociability, walkability, and delight, and in the driver's of ease of driving and safety.

The sociability of a street is essential to its overall quality. Residential satisfaction is reflected in the level of social interaction that takes place on a street and creates feelings of security and belonging. Street activity cannot be designed but can be encouraged by certain street characteristics. Heavy traffic would have a detrimental effect on the sociability because of its noise and pollution from exhaust fumes. If a street pattern encourages speed through widened streets, the sociability will consequently suffer. The best street patterns to offer sociability would be the discontinuous street patterns, which have a consistently lower rate of accidents and a higher level of perceived security.

Walkability by its very nature conjures up an image of comfortable access to local amenities and services. Street patterns can affect the location of these amenities but are not determined by them. Loops and lollipops and cul-de-sac street patterns do not lend themselves to walkability; these street patterns can be confusing, laborious, and discontinuous. Collector and arterial streets do not aid walkability either, because they are perceived to be inhospitable and unsafe with their high traffic volume, which naturally discourages pedestrian use.

Recent subdivisions have actually gone back to the original grid plan to create safe and more direct pedestrian routes, yet, quite often, the local amenities available to the community are beyond the acceptable five-minute walking distance preferred by people according to design guidelines. For walkability to be accepted, it requires a conducive street pattern and a reasonable arrangement of land uses.

Aesthetically, any street encouraging pedestrians along its way must be a source of delight, often meaning a street that has been pleasantly landscaped and easy to negotiate. Green space in any form is acknowledged as having social and health benefits; hence, the inclusion of green spaces in any development is further enhanced if the development is next to or close to parks or open spaces. These green spaces also become an oasis, providing safe playing spaces for children, an area for informal contacts, and a place for relaxation.

Open green space also has a beneficial environmental effect. It keeps the air cooler, retains rainwater, and recycles carbon dioxide, and is a key element of quality in any residential area or development. Residents have been known to accept an

increased density of houses so long as quality open space is provided as part of the development.

A motorist expects as much pleasure from driving as a pedestrian expects from walking. Street patterns that are usually liked by pedestrians are loathed by motorists and vice versa. For motorists, unimpeded traffic flow, perceived safety, and good visual aspects make the driving experience more pleasurable. These qualities are achieved by reducing and simplifying intersections, increasing lane widths and widening curves, and completely separating opposing streams of traffic by man-made or natural dividers. However, the road that best encapsulates these desires is the urban parkway, the least favorable to the pedestrian.

Street patterns, evolved and driven by one form of transport without taking into consideration all the various forms of transport, have led to cities becoming congested and undesirable as places to live. People who live in suburban areas are now faced with the consequences of these actions.

Retrospectively, planners are recreating livable city centers and redesigning suburbs to take into account the changing environment now being faced. Better public transport links and refurbishment of inner-city offices into apartments are just two of the many facets being considered, as well as the redesigning of street patterns to meet new requirements being demanded by the public.

Streetcars/Trolleys

Street railways were introduced first in New York in 1832, as a way of improving the productivity of horses, which provided the traction for omnibuses and coaches. On dirt roads, which in wet weather turned to mud, a horse could pull at most 10 passengers. Mounting the vehicle on smooth iron rails allowed one horse to pull 40 passengers. This reduced operating costs and allowed lower fares to attract more passengers, though still mostly wealthier residents. Horse-drawn streetcars or “horsecars” appeared in all major American and European cities by 1880.

Horses, though, fell ill and their food costs fluctuated, so various methods of mechanical traction were tried, including steam engines, compressed air, battery power, and cable haulage, of which only systems in San Francisco, California, and Llandudno, Wales, still remain in operation. The great step forward was the application of electricity via an overhead cable, powering motors. Frank Sprague demonstrated the trolley pole system of power collection in Richmond, Virginia, in 1887. Overhead wires and the practical trolley pole revolutionized the way in which streetcars could be powered.

With this new technology, and unlike horsecars, there was no practical limit to the distance that electric streetcars could operate, allowing horse streetcar lines to be extended into the growing suburbs and then enabling larger (eight-wheel) streetcars to replace small four-wheelers. Both of these further reduced operating costs and made streetcars the first mass transportation system.

Cities could now expand to house larger populations and new industries. Developers worked with streetcar companies to build new houses along extended streetcar lines, which benefited from the increase in traffic. For the first time in history, ordinary people did not have to live within walking distance of their place of work, and housing developments provided a better environment than that around inner-city factories.

Function

Streetcars also provided the means for people to reach a wider range of jobs and services than was possible when walking was the only affordable means of transportation. Early on, streetcar lines concentrated upon the twice-daily movement of

workers. Quickly, it became clear that the tidal flow of commuters presented economic problems for operators. Commuter traffic required a large number of streetcars and staff, which were not fully used outside peak hours.

More enterprising streetcar companies soon introduced measures to stimulate traffic during the off-peak times when there was spare capacity. Then the extra cost of carrying passengers was marginal. Low-price off-peak tickets, day tickets starting after the morning peak, and similar travel incentives were introduced. Some streetcar lines also carried parcels and letter boxes to give better access to the postal system and to generate additional revenue.

The function of streetcars was eroded by the advent of the motor car and the surfacing of roads. At first only the wealthy could afford cars, hardly making a difference to streetcar traffic. After 1920, when mass production brought down the cost of automobiles and new oil fields the cost of fuel, an increasing number of streetcar passengers bought cars and stopped riding streetcars.

This had two adverse effects on the finances of streetcar lines. The loss of passenger traffic and revenue to automobile trips weakened the financial position of streetcar companies, who were forced to defer maintenance or replace old streetcars with modern vehicles. The second adverse effect was the increase in traffic congestion caused by the anarchic traffic conditions created by automobile traffic. This slowed streetcars and made timetables unreliable, causing even more passengers to switch to cars.

A minor reversal was achieved by the Presidents' Conference Committee (PCC) in 1929, investing in a new and modern streetcar design to provide a better service at lower cost than old streetcars. This standard PCC streetcar was soon being built by a number of U.S. manufacturers, and by 1940 over 5,000 were in service in North America, giving a new lease on life to the remaining streetcar lines—and automobiles a run for their money.

Social Stratification

When streetcars were horsedrawn, they were the preserve of middle-income groups, who could afford to buy edge-of-town houses and pay the streetcar fares to reach their downtown offices and shops. With electrification, streetcars became the travel mode of lower-income groups, although

middle-income passengers continued to ride until they switched to automobiles.

Some streetcar systems tried offering different classes of accommodation, for example with separate “first class” cars, with upholstered seats, curtains, and ample light. Other operators set aside parts of streetcars for first class passengers, separate from the majority of passengers. By the close of World War II, however, most street railways were facing deep financial difficulties and by the 1960s most streetcars had been replaced by rubber-tired diesel buses.

The reintroduction of the streetcar in Portland, Oregon, and other cities like it has been driven as much by tourist traffic and their downtown movements as the need for a serious method of transport. Cities like Boston, Philadelphia, and Toronto that never abandoned streetcars are looking to expand and improve networks to current European practice. It is true to say that streetcars are a more widely acceptable mode of transport across income groups than buses.

Perception

Both buses and streetcars run along city streets, so why is there a difference in perception and social acceptability between them? Part of the reason is due to the quality of service provided and part to the urban fabric. By running on tracks, streetcars follow paths that have been designed to give the most comfortable ride, with gentle and controlled side jerking, for example. Streetcar drivers operate a vehicle where the dynamics are also preset to give the maximum of passenger safety and comfort. There is no known case of an automobile driver shooting a streetcar driver for getting in his way.

Another part of the difference in perception between buses and streetcars is the fact that streetcar tracks are a permanent feature of the urban infrastructure. Indeed, in some cities like Philadelphia, abandoned streetcar car routes still have the tracks in place, for example, to Germantown, and so could easily be reopened. But mainly, streetcar tracks signify that the service will be there into the future. Buses, on the other hand, are “flexible,” and users know that their routes can change or be withdrawn on short notice.

This is despite the fact that in many cities bus networks have remained static for many decades, reflecting the more glacial changes to the urban

economy and its infrastructure. But people who have cars, and therefore the ultimate flexible travel mode, ironically look for permanence in transit. One study in the United Kingdom asked respondents about their willingness to buy a house near different modes of transit for access to commuter trips to work. Well over 80 percent would buy a house near an electric rail line, about 50 percent near a nonelectric rail line, and less than 20 percent near a bus stop.

Routes

Historically, streetcar routes followed the main streets of the city that carried the most traffic. Network synergy was provided by having streetcar stops at intersection corners and by issuing transfer tickets. Those cities still operating streetcars have such operating patterns, although with routes not on each main thoroughfare, as retrenchment has led to the abandonment of less busy lines.

The function of a streetcar system is to carry passengers, and therefore serving major traffic flows makes a lot of sense. Newer streetcar lines such as those in Portland tend to provide downtown distributors, allowing tourists especially to get around the city center and to enjoy the major tourist attractions.

A new streetcar system to serve a metropolitan area should follow light rail transit (LRT) practice and seek out the routes with the densest automobile traffic. Rarely does it make sense to replace a bus line with streetcars unless the route also has heavy automobile traffic. For a metropolitan area, the designation of routes is one part of planning. The other part is the identification of optimum places for interchanges between routes, to maximize the utility of the whole network through synergy.

Historically, the downtown area of a city had the largest concentration of economic activity and employment and the densest development. Today that is not always the case, and often there is more traffic between suburbs than to the central business district (CBD). In relative terms, because the CBD is usually geographically smaller than most suburbs, serving the CBD will still be a key traffic objective.

Where new rail systems have been built in the last 20 years, often the incentive has been underused potential of the CBD, limited by available parking and the capacity of access roads. Building freeways to the CBD is expensive and often

counterproductive, whereas streetcar lines can significantly increase the passenger capacity of existing roads, without the need for demolition, and can free up CBD parking for more value-added economic activities.

Services

When passengers were captive to streetcar services, due to a lack of an alternative such as a car, the operator did not need to provide too high a quality of service, except to avoid overcrowding and passenger congestion at stops. Now most people have at least one car, which can be used whenever needed to go anywhere. So streetcar services must cater to the perception of automobile users. This can best be done by having a high-frequency service, so that passengers may “turn up and go” without having to know a timetable, and operating at a high level of reliability, so that a streetcar trip is more dependable than an auto trip.

Both of these service characteristics require a large fleet of streetcars and therefore high operating costs. However, operating costs can be reduced if operating speeds can be increased, so that fewer streetcars can make more trips. Here the cooperation of the highway authority is needed, since it makes little economic sense for a streetcar with 100 passengers to be held up at a road intersection with traffic signals to allow 10 cars with 15 passengers to cross.

Giving streetcars priority at road intersections, such as by preempting traffic signals so that streetcars can cross nonstop, can provide a significant improvement in operating speed. Similarly, in busy roads, giving streetcars exclusive lanes so they do not have to queue in congested times with other traffic also improves operating speed. Both these priority measures also feed back into improving the perception of car commuters to the benefits of using streetcars as an alternative method of getting to work.

Policy Coordination

It is clear from studies in many cities that the utility of transit investment, for example, in a streetcar line, can be increased by coordination with other land use and economic policies. Approving new higher-density developments along streetcar lines provides more potential passengers, which can then make the transit service more attractive. Allowing

A streetcar running on electricity delivered by overhead cables in Lisbon, Portugal, in 2013. One study found that more than 80 percent of people would buy a house near an electric rail line, compared to less than 20 percent near a bus stop.

commercial developments in the CBD, which has less (or no) car parking, also provides an incentive to access the completed new development by transit. This can be further enhanced if an out-of-town park-and-ride facility on the streetcar line is built, widening the CBD catchment area and enhancing the CBD environment by having less motor traffic and toxic air pollution.

Coordinating such policy initiatives can sometimes be difficult in that a streetcar line can be planned and built in under five years, whereas land use transformation can take 10 to 15 years. So how can transit and land use developments be kept synchronized? This is especially difficult if different agencies are responsible for land use development and transit. A private developer may have permission for a new downtown shopping mall

but will not start until the streetcar line is built to guarantee that customers can arrive. Then there is a dip in the economy and the retail market looks weak, so the streetcar line operates with fewer passengers and a bigger loss—should the shopping mall developer pay?

Maintenance and Repairs

Transit has to be 100 percent reliable if it is to attract and retain patronage. This means a rolling program of preventive maintenance. Streetcars can be repaired one at a time in the depot out of sight of passengers. A fleet with spare vehicles will ensure that the advertised service frequency can always be maintained.

Infrastructure is another matter. Often the track is damaged not by streetcars but by heavy road vehicles. The question is, then, how and when to repair tracks. If the damaged section is short, then one working line can be adopted, using temporary crossovers. This allows the service to operate, with hardly any impact on the passengers in terms of longer waits or rides. If the line is circular, then operation in one direction can be used while repairs are carried out. This does impose some inconvenience on passengers, from longer journeys on average to overcrowding, unless all the streetcars operate in the one direction. For a CBD-based streetcar line, the average journey will only increase by a minute or two, still much faster than walking.

For the routine replacement of worn tracks, all too often transit operators shut down the service for the duration of the replacement. With planning and careful scheduling, overnight replacement of worn tracks can allow streetcar services during the day without any interruption of service. This may cost more than closing the service and doing the repairs in one operation, but that ignores the loss of passenger goodwill and revenue.

Modal Competition/Coordination

There is no city in the world where car traffic is controlled administratively. There are examples of traffic management, either by physical measures (for example, traffic signal control, parking restrictions), or by fiscal measures (like charges to enter the CBD, or for on-street parking). Therefore, the main competitor to transit service is the private automobile. To improve transit's market share, therefore, requires competitive actions to attract some car trips.

Price is rarely the most effective way to attract auto trips, since car commuters spend a significant part of their income for the convenience and prestige of a car. In most market research exercises, service characteristics like reliability, journey speed and convenience rate more highly than transit fares as the measures needed to attract trips. Taxis, after all, are an important transport service in most cities, at fare levels much higher than transit.

Too often transit fares are set for political reasons rather than a clear assessment of market characteristics. Higher fares would allow investment in improving transit services, for example, by faster speeds, higher frequencies, and new stops more convenient for parts of the city not well served. In one study, new stops were found to give the best and biggest payback, often in a few months, by virtue of attracting passengers who previously were unable to use transit.

Competition between transit modes is rarely serious, even in cities where on-street transit competition is allowed. One example was in Sheffield, in the United Kingdom, where a company started a bus service at half the fare of the parallel streetcar line. The bus service lasted only six months and then was withdrawn for lack of bus passengers. In most cities, different modes of transit can and should be coordinated. Buses should feed and distribute rail and streetcar traffic. This is most effective with "cross platform" interchanges and through shared ticketing.

Civic Objectives

The most fundamental question over the introduction of a new streetcar line or system is what the objective to be fulfilled is. In public projects, objectives like raising profile, economic regeneration, and reducing social exclusion are often part of the rhetoric. If the capital costs and running costs are being met entirely from public funds, these can be legitimate objectives. If, however, the streetcar line is not being subsidized in its operating costs, then the attraction of passengers paying a fare must be included as an important objective. Making an assessment of the number of passengers to be carried and the fare they are willing to pay is a critical part of the calculus.

Politicians like low fares, which win votes. However, in an environment where passengers have travel options, fares may not be the most important

lever, since in most transit systems fare elasticity is usually about minus 0.3. This means that reducing fares by 10 percent increases the number of riders by only 3 percent, so the revenue is reduced by 7 percent, increasing the need for subsidy.

There is no doubt that a transit system can be a unique reflection of a city. With mega companies dominating retail and other businesses, there is a danger that cities can begin to look alike. A transit system can be a city's signature. It is therefore not surprising that in many European cities, souvenir postcards increasingly feature the local streetcars.

However, recent events have resulted in student safety becoming a major issue. Even in quiet neighborhoods, parents are worried that their children may be in jeopardy. It is reasonable for them to feel that way in view of school shootings, bomb threats, and the specter of domestic terrorism. Correspondingly, teachers are being trained on how to respond if the worst should happen at their school. They are told where to take the students in the event of an emergency and whom to contact. With all of the headlines about high-profile tragedies, teachers and administrators are more aware than ever of their roles in protecting students from harm during school hours.

Yet, many individuals have expressed that student transport between home neighborhoods and schools can be a weak point in the process of protecting student safety. When students as young as elementary age travel between their house and their school, there can be safety risks, which vary according to the method of student transport employed. There are also benefits to each method, which include walking, being driven by a parent or friend's parent, and riding a bus.

Walking

Children often enjoy walking to school and so have a personal motivation for doing it. They know that much of their school day will involve sitting at a desk, and walking to school gives them an opportunity to stretch their legs and expend some of their boundless youthful energy. It can also be good exercise, which is an incentive for parents to allow it.

The appropriateness of children being permitted to walk to school individually is, in part, a factor of their age. Older children are more likely than younger ones to be safety conscious along the way. That includes waiting for walk signals and looking both directions when crossing the street. Unfortunately, younger children may forget to do so. As every parent with small children knows, impulsiveness may supersede following what they have been taught about being cautious.

The same safety consideration holds true regarding strangers along the way. Older children will probably heed what their parents have told them about not talking to strangers, but younger ones may not. For these reasons, it is recommended to not let younger (or more immature) students walk to school alone.

Student Transport

In the past, teaching about safety concerns in schools was largely focused on telling students not to run in the hallways or mishandle scissors. Many communities used to feel secure that any major safety problem was improbable and could be proactively addressed by teaching good conduct to students. The biggest potential threat was fire, and so there were periodic drills to prepare for that scenario.

Even with older students, it is generally advised to have them walk to school in groups. Given that they are social creatures by nature, this will be welcomed by the students and will offer them a chance to talk with friends while in transit. If each walking group is comprised of at least five students, that will ensure that there is always a group to walk with even if one or two are home sick on a particular day. Before they first start walking together, all of their parents can go over safety rules with them. That way, they can remind each other if one forgets.

Another popular option is having a parental escort walk with the group of students each day. This underscores another good reason to have several students in a walking group, as opposed to just one or two. When you have several students, you will have at least that many parents to take turns as escorts. In neighborhoods where potential dangers are particularly concerning, having a parent provide an escort can assure the safety of all students in the group. Additionally, each parent only needs to volunteer at most one day each week for all the school days to be covered.

Of course, this requires all the parents to be willing to contribute at least some of their time to this effort. Most will be happy to, realizing that they are protecting their children and their friends. This approach to school transport has the advantage of providing safety while still allowing for the benefits of fresh air and safety. It also helps build a mutual support network among parents.

Driving and Carpooling

Especially with school safety issues in the news, many parents have decided that they must drive their children to school every day. This is perfectly reasonable and has multiple advantages. One is that it fosters a connection between parent and child at the beginning of each day, when both are fresh and wide-awake. This can be a major social benefit, with the parent and his or her daughter or son talking about the new day and what they plan to do. Some parents find this to be a good enough reason by itself to drive their children to school each day.

Safety is also a good reason. After all, a parent who drives his or her children to school does not have to worry about things going wrong in transit. They know that their child is safely delivered to the school, signed in, and securely with their teacher. Several decades ago, this might have seemed a little

overprotective, but in light of modern dangers it is perfectly sensible.

Driving their kids to school every day is not viable for every parent, however. Because of that, carpooling has become an increasingly popular option. It allows for the same high level of safety that a parent driving their own kids to school does. Just like in that case, parents know that the children are with a trusted adult between their house and school and are being kept safe and brought to their teacher. It also shares the duties among parents, just like taking turns as escorts for walking groups does. Correspondingly, a carpool group having four students will help ensure that at least one of their parents will be available to drive every day.

The Bus

There are few sights in elementary education more iconic than the big yellow school bus. If used well, it can be a secure method of student transport. One advantage is that the bus driver will probably have had a thorough background check to confirm both character and driving safety record. Parents who have any concerns can verify the background check process with their school district.

Disadvantages of riding school buses include what many people remember from their own childhood: they tend to be crowded and noisy. If the driver is the only adult on board, his or her attention will be primarily on the road. This means that the driver may not be able to address all incidents of nonconstructive conduct by students toward their peers. This can be a significant concern, especially with current awareness about the dangers of bullying.

One way to address that concern is by having schools specifically designate specific children as safety monitors. These older students, who have demonstrated their responsibility to teachers at school, can help ensure that the conduct of others is safe and healthy. If anything comes up that they cannot address with reminders to those acting out, they can inform the driver, who can talk to those having trouble. With this oversight process in place, student safety is enhanced for everyone.

Of course, even the older students can be subjected to peer pressure and may falter in their duties. For that reason, an additional safety measure on buses involves parent volunteers. These volunteers can also monitor behavior and carry more authority

than student safety monitors do. Their presence is likely to preclude not only overt bullying but also inappropriate language. They can congenially communicate the need for respect among students while serving as good examples themselves.

While those precautions help protect the safety of those on the school bus, there is still the matter of getting on and off the bus to consider. All of the considerations noted in regard to safety for walking groups apply to going to and from bus stops. If possible, children's parents can walk them to the bus stop at the beginning of each school day and meet them at the bus stop when they come home. That way, there are no periods in which the children are without a trusted adult. As with carpooling, parents can take turns doing this by forming a network with the moms and dads of their children's friends.

Taking children to and from the bus stop is one part of the equation when choosing to use buses. The other key part is making sure the children get off and on buses at school securely. Different schools may vary in their procedures for this. Some may have teachers meet buses in the morning and deliver students to buses at the end of the day. This is the safest approach, since the teachers are then able to verify each student getting on or off the bus when they should. Other schools may let students get on and off buses unescorted or have an older student in a safety monitor role during these transitions. Parents who are uncertain of how this is handled can inquire of the school and even be present when it happens to see for themselves. That way, each parent can make a decision for themselves as to whether they are comfortable with the level of safety they see. If they feel that there is insufficient organization or safety, they may want to pursue a different method of student transport for their children.

Looking Forward

All of these approaches are being looked at more closely than ever, with parents and teachers weighing the benefits of each. All of them want the students to be safe, though they may have differing opinions about how to best accomplish that. Teachers and parents who have been very involved with the school may feel that traditional buses are perfectly fine. Parents who are particularly concerned about the neighborhood or want bonding time may feel that driving their kids personally is preferable.

Still others are focused on the benefits of letting their children walk, while emphasizing the benefits of safety in numbers.

Whatever the student transport choices made by particular families, it is generally accepted that safety should always be the first priority. First and foremost, this involves ongoing conversations in each family. Those conversations include how to keep safe and act safely toward others. They also necessitate talking about potential dangers and about what to do in challenging situations.

At schools, many of the same conversations are happening in classes between students and teachers. There, the discussion includes following school procedures and policies like always, checking in with adults in charge. Parents, teachers, and children are conversing together to make sure that traveling to and from school stays a positive and safe experience for all involved.

Subway Systems

Subways have a significant impact on the growth and success of today's cities. Subway systems in Tokyo, Seoul, Shanghai, Beijing, Moscow, London, Paris, and Tokyo have played critical roles in their economic development in recent decades. While already existing in American cities including New York, Boston, Philadelphia, Washington, D.C., and

Los Angeles, old subway systems can be revitalized or combined with new systems to stimulate economic progress. Cost, development and infrastructure problems, administration including expansion and contraction of governing authority and territory, and ridership are key issues facing subway systems worldwide, despite their history and contemporary operating procedures.

Subways in Asia

The Tokyo subway is part of a widespread rapid transit system that covers Japan's Greater Tokyo area. Although the Tokyo subway operates mostly within the central city, its lines extend onto suburban railway lines so that in 2013, the entire Tokyo Metro and Toei Subway system, had 290 stations and 13 lines, together carrying an average of over 8 million passengers a day.

The two primary subway operators in Tokyo are Tokyo Metro, formerly Teito Rapid Transit Authority, which was privatized in 2004 and operates 184 stations and nine lines. The Toei Subway, an arm of the Tokyo Metropolitan Government operating under the Tokyo Metropolitan Bureau of Transportation, operates 106 stations and four lines. They have different fare structures. Although Tokyo Metro and Toei Subway systems feature a unified system of line colors, line codes, and station numbers, they have different operating obstacles to overcome, including differences in fares and separate administrative bodies, infrastructures, and policies.

Other subway systems, including the Seoul Metropolitan System, operate under one authority but still face similar problems—like breaking even and overcrowding. Consisting of 19 lines, the Seoul Metropolitan Subway system in South Korea opened in 1974 and enables its 5.6 million daily riders to reach their destinations safely and quickly, while operating at just a minor loss. The Seoul Subway System is noted for its cleanliness, passenger-friendly features, and use of advanced technology such as Internet access, digital TV screens, automatic payment systems, and climate-controlled seats. Planners are projecting extended lines and services from 2013 to 2018, including hookups with the Incheon 2 and other lines.

In China, the state-owned Beijing Mass Transit Railway Operation Corporation, with 14 lines, and the public-private joint venture with the Hong

Kong MTR, with three lines, operate the Beijing subway, which is the oldest metro system in mainland China. The Beijing subway is the third largest in the world in annual ridership after Seoul and Moscow, with 2.46 billion trips in 2012 and an average weekly ridership of over 10 million. Beijing city planners addressed the city's ongoing traffic congestion problem by scheduling construction plans for additional lines to begin before 2015.

In 2012, Ying Minghong, board chairman of Shanghai Shentong Metro Group Co., which operates Shanghai's subway, stated in *China Daily* that Shanghai's subway system operated in the red. China's longest subway network, with 11 lines totaling more than 265 miles, the Shanghai Metro system totaled 354 miles by 2013 and is predicted to reach 544 miles by 2020. Shanghai Metro had 2.1 billion passengers in 2011, but the system does not generate enough income to be self-sustaining, even with Shanghai's 23 million population. The chairman said that ticket sales and advertising income cover daily operating costs but they do not cover maintenance or the interest on loans, emphasizing that other subway systems including the Moscow Metro had the same problem.

Russian and Western European Subways

As of 2013, the Moscow Metro operated 190 stations featuring décor illustrating Russian architecture and art along a 197.3-mile route, and carried about 6.6 million passengers a day. Citing a 2012 to 2020 time frame, the Moscow Metro plans to expand by almost 93 miles, which will make it the third-largest metro system after the Beijing and Shanghai Metro systems. According to Moscow Metro chief Dmitry Gayev, revenue from fares, the main source of income for most tube systems, accounts for up to 70 percent of all the Moscow Metro's income, with the rest coming from state subsidies and other commercial operations.

In his book *Down the Tube*, transport expert Christian Wolmar stated that with 3.5 million passenger journeys a day, the London Underground could make annual profits without capital and structural improvements, but transport companies suggest that the cost of a ticket is what makes the difference.

The London Underground system's 250 miles of track and 270 stations serve most of Greater London and parts of Buckinghamshire, Hertfordshire,

and Essex counties. It has expanded to 11 lines and carried over 1 billion passengers from 2012 to 2013. As of 2012, passenger fares covered 91 percent of operating expenses.

After Moscow, the 133-mile, 303-station Paris Metro system is Europe's largest metro system, transporting a total of 1.524 billion passengers in 2011. The Paris Metro system is one of the densest metro systems in the world, with 245 stations within 34 square miles of Paris and featuring richly decorated art nouveau stations. When the Paris Metro network reached the saturation point after World War II, the system introduced newer trains to encourage high traffic, but since then improvements have been limited because of network design and the short distances between stations.

Metro systems around the world, including Montreal, Singapore, and Tokyo, adopted the Paris Metro's successful use of rubber-tired lines, and the Paris Metro also contributed the name *Metro* to worldwide systems.

Subway Systems in the United States

As the United States becomes increasingly urbanized, with 79 percent of its population living in urban areas, subways provide an efficient way to swiftly move large numbers of people and reduce pollution and congestion. Long-established subway systems in New York; Boston; Philadelphia; Washington, D.C.; and Los Angeles face the challenges of expanding and profiting into the 21st century.

One of the world's oldest public transit systems, the New York City Transit Authority contains 209 miles of routes and in 2012 averaged over 1.65 billion rides. Measured by annual ridership, the New York City subway is the seventh-busiest rapid transit rail system in the world behind the metro subway systems in Tokyo, Seoul, Beijing, Moscow, Shanghai, and Guangzhou.

As of 2013, the New York subway was comprised of three formerly separate systems that competed with each other and finally merged. August Belmont's Interborough Rapid Transit Company and the Brooklyn Manhattan Transit Corporation were privately owned and the city of New York owned and operated the independent subway system. All three were consolidated into the New York City Board of Transportation on June 1, 1940. In 1953, the New York City Transit Authority was created as a public benefit corporation to acquire the transit

facilities and operate them for public convenience and safety. The city of New York owns the New York City Subway and leases it to the New York City Transit Authority, a subsidiary agency of the Metropolitan Transportation Authority.

The Massachusetts Bay Transportation Authority (MBTA) operates all of Boston's five major types of transit vehicles: regional (commuter) rail trains, heavy rail transit (subways and elevated trains), light rail vehicles (trolleys), electric trolleybuses, and motor buses.

The MBTA applied for some of the first federal funding for modernizing 10 mass transit stations, and since 1965 it has received over \$3.5 billion for capital improvement projects along with its yearly operating program. In 1980, the governing structure of the MBTA again restructured to meet changing needs of the system. A seven-member board of directors appointed by the governor and two additional members from outside the MBTA District, along with the secretary of transportation serving as chairman of the board comprise the MBTA's governing board. The state government pays the largest share of the annual operating deficit, with fare box revenues covering about 31 percent of the authority's annual operating expenses. Measured by daily ridership, the MBTA is America's fifth-largest mass transit system with an average weekday ridership of approximately 1.3 million passenger trips.

The Southeastern Pennsylvania Transportation Authority (SEPTA) is a metropolitan transportation authority that operates bus, subway, elevated rail, commuter rail, light rail, and electric trolley buses serving 3.9 million people in the city of Philadelphia, and in Delaware, Montgomery, Bucks, and Chester Counties. SEPTA also serves New Castle County in Delaware and Mercer County in New Jersey. SEPTA is one of the only two U.S. transit authorities that operates the five major types of transit agencies, along with the MBTA. By ridership, SEPTA is the sixth-largest rapid transit system in the United States, with 280 active stations over 450 miles of track and 196 routes. It also manages shared-ride services in Philadelphia and Americans with Disabilities Act services across the region.

In 1966, the federal government passed a bill to create the Washington Metropolitan Area Transit Authority (WMATA), covering the transit region of the District of Columbia, Virginia, and Maryland.

The WMATA administers the Washington Metro subway and also operates a Metrobus, which serves Virginia and Maryland. The Metro network includes five lines, 86 stations, and 106.3 miles of track, and had a 2012 ridership total of 280,904,200 people.

Los Angeles is another city that has adopted a transit system consisting of separate lines operated by one governing authority. Operated by the Los Angeles County Metropolitan Transportation Authority, the Los Angeles Metro Rail system consists of six lines serving 80 stations in the Los Angeles County area with a June 2012 average daily weekday ridership of 362,904 passengers. The lines include the Red and Purple subway lines. The Transportation Authority plans several extended routes for the near future.

County and regional planners cite the lack of a continuity of congressional funds and the lack of motivation to invest in publicly funded infrastructure projects as reasons for the modest number of subway systems in America. In its briefing book titled *The Transportation Planning Process: Key Issues*, the U.S. Department of Transportation offers a blueprint for subway planning and creating policy and regional planning bodies.

Subways/Elevated Trains

A subway or elevated train system is one whereby the rail service is provided on an exclusive right-of-way, fully under the control of the train operator. The first subway line was opened in London, England, in 1863. The second was opened in Budapest, Hungary, in 1896. The first subway line in North America opened in 1897 in Boston.

The logic in free market societies was that the only way to escape the congestion of city streets was to build a separate transport network at a different grade from the ground, where congested city streets were to be found. Digging underground is expensive, so the less expensive option of building above ground led to elevated railways. The earliest of these were built in New York City in 1868, Boston in 1887, Chicago in 1892, and Liverpool, England, in 1893. Most of these elevated lines were built above existing streets. Some cities, such as London, did not allow such elevated lines because most streets were narrow, and such lines did not enhance the aesthetics of the urban environment.

Role of Grade Separation

Grade separation, whether in the form of a subway, elevated railway, or sometimes both—as in the most recent London Docklands system—is to give the train operator complete control of the system. This allows faster operating speeds and high-frequency services, with as little as one-minute between trains. This gives greater passenger capacities than can be economically provided by roads. Typically, a subway or elevated line operating at two-minute intervals can carry 30,000 passengers per hour. A highway with car commuters having the same capacity would need to be 21 lanes wide in each direction.

When the public purse is funding transit and road building, then subways or elevated railways are usually the more economic option compared to highway building. This analysis ignores the disruption to the city during construction and then permanently when opened. Boston's "Big Dig" showed this on a massive scale when Interstate 93 was diverted into a tunnel nearly four miles long through the city center. It turned into the most expensive road project in the history of the United States.

For both subway and elevated systems, passenger access is the most sensitive planning and design issue, with a trade-off between the high costs of each station and the generation of passenger trips. Stations can cost as much as track tunneling costs for a subway system. There is, however, an upside to station provision, as was first discovered after the Yonge Street subway line opened in Toronto in 1954, and more recently the London Docklands line. Property values increase adjacent to subway/elevated stations, thanks to the improved access provided.

In Toronto, this led to an increase in property tax revenue, which in less than 20 years paid for the Yonge Street subway line. In London, the value of land by the yet-to-be-built Docklands line increased within three months by more than the cost of the London Docklands line. As the land was in public ownership, the net cost of the London Docklands line was remarkably low, although separated into different departmental accounts.

Markets Served

Subways (and, to a lesser extent, elevated railways) are built to serve the central business district (CBD), which has the highest concentration of economic activity in a metropolitan region. This means that the traffic on such lines is heavily peaked, with spare capacity at other times.

With the growth of leisure and tourism, this spare capacity is often put to good use by offering special tourist tickets, which are only valid after the end of the morning peak. Subway systems are usually the most easily used transit system by visitors to cities, who are not familiar with the local topology. This has been reinforced by the widespread use of schematic network maps, first introduced in London, England, in 1931. Such schematic maps make system navigation easy, as long as the name of the destination station is known.

The St. Patrick Station on the Yonge–University–Spadina line in Toronto, Canada, in 2008. After the opening of the Yonge Street line, nearby property values and resulting tax revenues increased enough to pay for the subway line in less than 20 years.

While most subway and elevated railway passengers have automobiles available, the density of the CBD may make driving to work impossible, both as road capacity is limited and parking space even more so. A study in 1963 showed that central London would have to be rebuilt on at least three levels, with roads occupying the ground, parking the next two levels, and above that the economic and other activities which presently constitute the CBD. This clearly was not realizable. So access to the CBD of London is 80 percent by rail, and only 20 percent by road. Moving one million commuters during the peak two hours by road would be impossible. This role is reinforced by park-and-ride and kiss-and-ride facilities at suburban stations.

London is a rail-dominated city, with 70 percent of all British rail trips to or in London. A similar

pattern can also be seen in the United States, where nearly 60 percent of commuter trips in New York are by rail, and nearly 70 percent of all U.S. rail trips are in New York.

The CBD is therefore the reason for subway and elevated lines in the first place, and also a mechanism for reinforcing the role of the CBD by making it the most accessible part of the metropolitan region, as the prime “central place.” Secondary urban centers are usually linked to the CBD by the subway.

The increasing density of CBD development is now threatening subways, both in terms of general overcrowding and also at specific stations. Such overcrowding can lead to temporary station closures on safety grounds. Many cities are now embarking on ambitious plans to add subway capacity, with new lines, stations and interchanges, increasing network synergy and also redundant capacity in the case of a temporary line closure.

Station Location and Access

Stations are mini central places, changing the morphology of the urban environment. Stations can therefore benefit from the activity of existing urban subcenters, or by creating new ones. This provides a unique planning opportunity for strengthening the urban economy, unlike a highway interchange, which occupies a large area and is normally not accessible to pedestrians.

Not only do new subway stations have a transport and interchange function, they are also items of architecture and public art. Where a station is integrated with an “air rights” development, the station must not be lost, like an appendix to the building above. Many new transit projects devote 1 percent of their construction budget to public art. If the architectural design of new stations is also considered public art, the impact can be much greater.

Interchange With Other Modes

Because of the high cost of construction and the need for high passenger flows, a network of subway or elevated rail lines will not provide comprehensive coverage across the whole of a metropolitan area. Therefore, with the limited geographical coverage possible from a limited number of lines and stations, it will be possible to attract only a small part of the metropolitan population living within walking distance. In order to provide a greater economic and social utility, some of the stations will

need to be configured to make interchange with other modes easy, especially car and bus.

Such interchange stations will normally be at or near the outer edge of the metropolitan area, so that most of the journey is made on the rail line. “Feeder” trips by car and bus will be short, both in distance and time. To make these interchange trips highly attractive will require the physical design of the interchange to be as convenient as possible. There are now plenty of examples in the United States and Europe to avoid the pitfalls and reap the benefits from successful designs.

For bus and ride passengers, the ideal is “cross platform,” with a timed connection, so there is no waiting. There may also be scope for bike and ride interchange. At many European stations, hundreds of bikes are parked. Indeed, in some places, commuters have two bikes, one at the home end and another at the work end, for two bike rides with a rail ride in between.

Park-and-Ride or Kiss-and-Ride

In most developed countries the main feeder mode to interchange stations will be the private automobile, justifying a section in its own right. There are two ways in which this works. The majority of trips will involve the driver parking a car and riding the rail line. There will also be trips where the commuter is dropped off (kiss-and-ride), and the car driven away for use during the day, such as taking children to school.

Kiss-and-ride requirements should have the drop-off and pickup points close to the platform, for a minimum walk. Although commuters tend to go for a particular train, arrivals will be on a skewed distribution, before train departure, unless the service is very frequent (under five-minute intervals), when arrivals will be almost random. There should be space for about 10 cars at a time for drop-off, and the exit route should be clear and short to minimize the occupation and congestion of the interchange station area. The circulation of kiss-and-ride traffic should be separate from park-and-ride.

For park-and-riders, those who arrive earliest will park nearest the platform, so they have the shortest walk. In any case, there need to be clear and direct foot routes from all parts of the parking lot to the rail platform. Depending on the local weather and climate, these routes may also need to be protected from wind, sun, and rain.

Some park-and-ride interchange stations are also used informally by carpoolers. Three of four commuters drive to the interchange and share one car to work. While this does not provide any riders for the rail line, it does reduce the number of cars on congested roads, and the poolers may take advantage of high occupancy vehicle (HOV) freeway lanes. If the interchange is operating near capacity, this car-sharing use reduces the chance to increase transit use. How this is addressed will usually be a local solution. One solution is to charge for parking with a free transit return ride.

Air Rights Development

Subway stations are often constructed by “cut and cove” methods, resulting in the space over the station being available for other developments. Selling the air rights to high added-value activity uses will help to offset some of the construction costs. Other sub-surface parts of a subway line may not be in tunnel but cutting. Again there is an opportunity to exploit these spaces, but for lower-level activities, unless very near a subway station. In constructing a new line, such air rights developments can be integrated into the subway construction. When the Hong Kong subway was built, even the train depot air rights were exploited for high-rise apartments. Elevated lines rarely lend themselves to air rights developments, but may have spaces under the structure that can be used for ancillary economic activities.

Impact on Urban Economy

As many studies have shown, a subway can have secondary economic benefits for the metropolitan area many times greater than the cost of building the subway. Unfortunately, these benefits can rarely be captured directly by the subway builder.

In Toronto, after the first subway (the Yonge Street line) opened, real estate development around the stations recouped the investment in the line. Various proposals for “value recapture taxes” have been made but none so far have been implemented. Second best, then, is the rise in property values, and so local property tax revenues.

There are, however, other benefits. These include the stimulation of the CBD as an employment center and the multiplier effect that has throughout the metropolitan region—for example, by boosting local service and retail businesses in residential areas where CBD commuters live.

Social and Other Effects

Car commuting is inherently an unsocial activity. If a commuter has a family at one end and work at the other, there is a lack of social interaction during the journey to and from work, even including sharing gestures while crawling along a congested freeway. Transit can be a very sociable activity and certainly provides opportunity for informal friendships. This is especially true for regular commuters who graduate from eye contact, to smiles, greetings, conversations, and more involved interactions.

Studies have also shown that rail transit riders are usually healthier than car commuters. This is directly a result of regular exercise, even if only walking across a park-and-ride lot at one end of the trip and from the station to work at the other. Rail commuters are fitter than auto commuters, having a lower body mass index (BMI). There are also secondary benefits from reduced traffic and pollution. Transit commuters are also less likely to be killed or injured in auto crashes.

Improving rail transit can be one of the most cost-effective ways to improve public health, the tertiary benefits of which are a reduction in toxic air pollution and therefore a reduction in smog and cardio-respiratory diseases. This means less hospitalization and medication. Families could realize private economic benefits from released personal income, which can be used for other household consumption, further stimulating the local economy.

Policy

While a subway or elevated railway at its most basic is purely a mode of transport, it can also be used as an instrument of policy. Providing an alternative to auto commuting reduces traffic congestion and pressure to build more roads. Less auto traffic means less fuel consumed and less pollution created. Less pollution means less illness and death caused. In the United Kingdom, traffic pollution causes about 45,000 deaths per year. On the same basis, about a quarter of a million people in the United States are killed by toxic traffic emissions, about four times more than killed in auto crashes and firearms combined.

Subways can also be used to stimulate the local economy by strengthening the CBD, by releasing surface car parking for economic activities, and by prompting denser development that a transit service can support. Not only does this relate to

the CBD but also to each subway station, located at suitable central places, where similar land use intensification can occur.

Finally, a subway can be part of a health promotion package by encouraging people to walk, even if only across a park-and-ride lot. Additional exercise improves fitness and reduces obesity. Walking is also a good psychological stimulus. Also, the more sociable subway means there are more personal interactions and therefore the chance of better social influences.

Sulfur Dioxide

A noxious, poisonous gas with a strongly acrid smell, sulfur dioxide is a chemical compound that can originate from both natural and (human-made) anthropogenic sources. One of the sulfur oxides (SO_x) formed by the interaction of sulfur and oxygen, sulfur dioxide is also referred to as sulfurous anhydride and has the formula SO_2 . It may eventually be converted to the highly corrosive sulfuric acid (with a formula of H_2SO_4).

A colorless gas, SO_2 is an air pollutant with health risks for both humans and animals. Sulfur dioxide in the atmosphere contributes to smog formation, as well as acid rain. Additionally, it can negatively affect vegetation and damage structures. Therefore, efforts have been made to reduce the amount of SO_2 in the atmosphere. Despite the adverse effects associated with SO_2 , the gas also

has beneficial uses in industry, though not without controversy. It is, for example, used in the food and beverage industries, where it is utilized as a preservative for fruit, specifically to prevent fruits from becoming discolored and brown. The beer and wine industries also employ the use of SO_2 as a preservative. Additionally, it can be used to bleach materials such as paper and fabrics. It has also been used in wastewater treatment.

Sulfur dioxide impairs breathing function in humans. Upon inhalation, it acts to constrict the bronchi (passages that convey air into the lungs), resulting in chest tightness and shortness of breath. It may also form particulates (discrete matter in liquid or solid form) when it interacts with other atmospheric components. Such small particulates ($< 2.5 \mu\text{m}$) present increased health risks. They may be inhaled and, due to their minute size, become lodged deeply inside lungs, where they restrict lung function.

While everyone is subject to the dangers of inhaling both SO_2 and sulfur-based particulate matter, some populations are especially vulnerable. Asthmatics, sufferers of bronchitis, emphysema, and heart disease, along with young children and the elderly, are particularly sensitive to damage from SO_2 . Lung function in the presence of SO_2 is made worse when breathing is predominantly done through the mouth, as often occurs during exercise.

Various organizations, such as the U.S. Environmental Protection Agency (EPA) and the World Health Organization (WHO), have issued guidelines reflecting unsafe concentrations of SO_2 in the atmosphere. These limits are used to indicate air quality by describing when air pollution (by constituent) can be assumed to result in health consequences.

The WHO revised air pollution guidelines, including those for SO_2 . Concentrations should not exceed $20 \mu\text{g}/\text{m}^3$ based on a 24-mean (or $500 \mu\text{g}/\text{m}^3$ based on a 10-minute mean), reflecting new information on the health impacts of SO_2 inhalation. The EPA, based on the Clean Air Act, sets levels of permissible concentrations for a given set of atmospheric pollutants; these include SO_2 , which is defined as a primary standard (because of its damaging effects on human health). The National Ambient Air Quality Standards (NAAQS) lists this level as 75 parts per billion by volume (ppb) for a one-hour averaging period. A secondary standard of 0.5 parts per million by volume (ppm) is designed

to protect humans indirectly (by protecting flora, fauna, and built structures); this standard utilizes a three-hour averaging time.

The largest and most important natural source of SO_2 is volcanoes. When volcanoes erupt, they release a number of gases along with solid, discrete particles, called tephra. Sulfur dioxide is one of the most abundant gases released during an eruption, after water vapor (H_2O) and carbon dioxide (CO_2). Other natural sources of SO_2 include the decomposition of vegetation in wetlands or oceans.

Wildfires can also release this gas into the atmosphere, although wildfires can be caused both naturally and anthropogenically. The amount of naturally occurring SO_2 is, however, greatly overshadowed by that entering the atmosphere through human activities. Therefore, any conversation about reducing the amount of this toxic gas in the atmosphere requires an examination of human-induced sources.

Industrial power plants that burn fossil fuels (i.e., coal) are the largest anthropogenic emitters of SO_2 to the ambient atmosphere, contributing over 60 percent in the United States. Coal contains sulfur. Therefore, an electricity generation plant that is fired by coal emits that sulfur into the air. The sulfur then reacts with oxygen, which comprises approximately 21 percent of air by volume. The result is the formation of SO_2 . Additional human-caused sulfur sources include heating of homes (with coal or oil), output from nonferrous smelters, paper manufacturing, and emissions from motor vehicles. Sulfur emissions into the atmosphere are related to both the levels of development and the populations of countries. More developed societies may generate more emissions, but they also have the wealth necessary to use mitigation technologies.

Sulfur dioxide contributes to the formation of a type of air pollution referred to as industrial or sulfur smog (not to be confused with photochemical smog). Industrial smog is primarily soot based and develops when a large amount of sulfur-containing coal is burned. This in turn interacts with fog to form a brownish-yellowish haze dangerous to humans. Indeed, this type of smog was responsible for the deaths of over 4,000 Londoners in the Great Smog of 1952. The Killer Fog of 1948 in Donora, Pennsylvania, was also attributed to SO_2 emissions from a proximate steel plant. Industrial smog is not a new problem, having been described for several centuries.

Sulfur dioxide erupting from Mount Kilauea in Hawai'i Volcanoes National Park in 2008. Volcanoes are the largest and most important natural source of SO_2 , which is the third most abundant gas released by eruptions after water vapor and carbon dioxide.

Acid Rain

One of the best-known consequences of atmospheric SO_2 is acid rain, discovered and named in 1872 by the Scottish chemist Robert Angus Smith, who worked in Manchester, England, at the time. Otherwise known as acid precipitation or acid deposition, the problem received much greater exposure in the 1960s after Svante Odén argued that industrial activity from other locations, specifically West Germany and the United Kingdom, were to blame for the deterioration of Swedish lakes.

Acid rain refers to precipitation that has a lower pH than 5.6, the approximate level of unpolluted rainwater. Typical rainwater is mildly acidic (from atmospheric CO_2 that dissolves in water, forming a weak carbonic acid). However, it can be rendered more strongly acidic by other components in the air, chiefly SO_2 and nitrogen oxide (NO).

When SO_2 emissions enter the atmosphere (largely from coal-fired power plants), they can react with various compounds. They interact with

highly reactive hydroxyl radicals (OH) and oxygen, ultimately being converted into sulfuric acid. This acid is then precipitated out of the atmosphere by rain, snow, or fog, a process called wet deposition. However, acids can be removed from the atmosphere via dry deposition, in which dry particles or aerosols, such as dust, act as carriers and bring acid to the Earth's surface. Acid rain, then, results in damage to both the natural and built environments.

Forests suffer, because acid rain weakens trees and the increasingly acidified soil provides fewer nutrients. Forest dieback (or forest decline) refers to the deterioration and death of trees (both of single or multiple species) and has been linked, at least partially, to acid rain and emissions of SO₂. Aquatic environments are particularly affected by the adverse effects of acid rain. Fish populations decrease because of fish kills, and surviving fish may have reduced body weights. Acid rain also impacts buildings, as materials such as limestone and marble become worn away at faster rates under the presence of acids. Sulfate particles associated with acid rain also contribute to reduced visibilities.

Emissions

Although SO₂ emissions lead to acid rain, the devastating effects are often felt far from the original sources of pollution. This is due to atmospheric transport of the gas and the particulates generated by its interactions with other compounds. Globally, SO₂ emissions have dropped, though there are regional differences. In both North America and Europe, for example, emissions have decreased, whereas they are rising in other places (for example, India). This diminishment is a result of various strategies employed to reduce the amount of SO₂ emitted into the atmosphere, such as utilizing natural gas (which contains much less sulfur than coal).

Another technique used to lessen emissions is the employment of scrubbers, which remove SO₂ before it is released into the air. This process, called flue-gas desulfurization, uses some alkaline material to remove the acidic SO₂ from the effluent of a smokestack. Scrubbers used in flue-gas desulfurization can be either wet or dry. Wet scrubbers employ liquids to remove the offending compounds (for example, SO₂) from a gas stream. Liquid droplets of a sorbent material absorb the SO₂, which is then treated to take out the pollutant. Spray drying is a method of desulfurization that also utilizes

liquid to extract SO₂; however, the liquid is heated and results in a powder.

Within the climate system, SO₂ has a cooling effect. Sulfate particles reflect solar radiation, preventing that energy from being absorbed and increasing temperatures. Volcanic eruptions high in sulfurous gases tend to cool the Earth's temperature, although the effect is generally small and short-lived (typically not longer than two or three years).

Historically, motor vehicle emissions contributed substantial amounts of SO₂ to the ambient atmosphere, particularly from diesel engines. Sulfur dioxide is emitted as a waste product of fossil fuel combustion. However, newer vehicles burn fuels considerably more efficiently and cleaner, thus adding fewer pollutants to the air than previously. Additionally, low-sulfur fuels, such as ultra-low-sulfur diesel (ULSD), are increasingly available to motorists, resulting in a decrease in SO₂ emissions. This fuel has greatly reduced amounts of sulfur but also produces lower fuel economy (a result of sulfur removal processes). Still, it is the predominant form of diesel fuel in Europe, North America, Australia, and New Zealand. Some countries (for example, China) have stricter sulfur limits in certain urban areas.

Ultra-low-sulfur diesel reduces emissions to the ambient atmosphere. Catalytic converters were introduced to vehicle manufacture to reduce air pollution from fuel combustion. Although vehicles may be equipped with these devices to make emissions less toxic, the converters focus on carbon monoxide (CO), nitrogen oxides (NO_x), and unburned fuel, rather than on sulfur.

Indeed, any sulfur in a fuel may oxidize to SO₂ in the conversion process. Therefore, utilization of fuels with reduced sulfur content is needed to minimize SO₂ emissions. Because the removal of sulfur is a costly process, urbanized areas in developing countries are particularly susceptible to the damage caused by SO₂ in the air.

Supernetworks

A supernetwork represents a network consisting of flows, links, and nodes that operate over and above existing networks. Such supernetworks undergird societies and their economies, affecting a variety of economic and social activities, chiefly those related to communication, energy, and transportation. Supernetworks are studied in a variety of related and overlapping disciplines, including economics, environmental studies, finance, logistics, telecommunications, and transportation.

Transportation networks permit individuals and organizations to conduct business operations across a wider spectrum than would otherwise be the case, while also allowing individuals to keep in touch with family and friends who may live a distance away. Transportation supernetworks have evolved from the formal study of the nodes, links, and flows involved in efficient network operations. The study of supernetworks and the modeling of more efficient ways to facilitate transportation permit better organized movement of humans, information, capital, and materials over space and time.

Background

Modern transportation networks come in a variety of forms, including roadways, rail, water, and air. Even in ancient times, however, transportation networks were often a topic of consideration. At one point, for example, the ancient Romans found their

roads overwhelmed by chariots and other users. In an effort to reduce traffic congestion, Rome's leaders instituted a time-of-day chariot policy, which prohibited chariots from using Roman streets during certain hours.

As the centuries passed and transportation grew more complex and complicated, examinations of its networks grew more sophisticated and interdisciplinary, as well. Scientific techniques and procedures have been borrowed from a variety of other disciplines, including biology, computer science, engineering, finance, and mathematics. These diverse influences feed the study of transportation supernetworks with dual outlooks, which combine both management and research goals and objectives.

Models and tools that have been developed with regard to transportation supernetworks are used by businesses, government agencies, and industrial groups to better design and implement ways to transport materials, goods, and people over large and small distances.

The formal study of supernetworks initially involved the development of quantitative models that represented nodes, links, and flows as mathematical equations. Over time, this evolved to include qualitative models, with a push to design algorithms that would solve the ensuing models efficiently and successfully.

Traditional problems that those studying supernetworks examined included shortest-path, maximum-flow, and minimum-cost-flow problems. Shortest-path problems involved determining the most efficient and cost-effective path from an origin node to a destination node. Maximum-flow problems entailed determining the greatest flow that could be sent from the origin node to a destination node without exceeding the maximum capacity of the links. Minimum-cost-flow problems required a balancing of both the costs and capacities associated with the links, so that supplies at the origin nodes could be shipped at minimal costs via the links without surpassing arc capacities.

Today, those who study supernetworks consider problems and issues that have changed little over the centuries, although the technology that permits transportation has changed dramatically. The problems and issues that supernetworks work to ameliorate include congestion, system and user optimization, operations, and network interactions.

Applications

The study of network systems known as supernetworks involves the interdisciplinary analysis of the complex interactions in and between economic, environmental, financial, knowledge-flow, public utility, social, supply chain, telecommunication, and transportation networks. Researchers construct mathematical models and computer algorithms that assist optimizing flows of resources and increasing efficiency with regard to transportation supernetworks.

Congestion, for example, greatly adds to the costs and reduces the efficiency of transportation globally. In the United States and Europe, congestion—crowding of the roads, tracks, waterways, or airports that delays flow—costs organizations and consumers well over \$250 billion per year in lost productivity. As the number of automobiles continues to multiply, supernetworks that can prevent impending gridlock on roadways can prove highly beneficial. To that end, researchers work in the modeling of congestion, as well as the development of appropriate policies for congestion containment, reduction, and management.

System and user optimization are also of interest within supernetworks. System optimization, which benefits society as a whole, may look very different from user optimization, which helps an individual traveler. This disparity exists because when selecting their routes and times of travel, users inevitably select the route and time of travel based almost solely upon a desire to reduce their own travel cost or time. These outcomes may differ from those of the system, which seeks societal goals.

As the system often has control over the flows of the network, it seeks to minimize the total cost in the network and thus reduce lost productivity as much as possible. Supernetworks, thus, are enmeshed in this noncooperation between system and users, and researchers investigate ways to maximize efficiency and minimize costs.

Actual results often differ from projections, however, a phenomenon known as the Braess paradox. This paradox, named after German researcher Dietrich Braess, explores how the addition of an additional link can sometimes result in a worsening of traffic flow, in contrast to what most models predicted. Conversely, the subtraction of an existing link can sometimes improve traffic flow rather than create the gridlock expected. The Braess paradox

assumes that the underlying behavioral principle is user optimization, and shows the necessity of planning and testing models before implementing changes in the transportation network.

Supernetworks are also greatly intertwined with operations, made more difficult because of the large-scale nature and complexity of many transportation networks. The underlying network topology can vary greatly from network to network. The model used by the regional Chicago transportation network, for example, consists of nearly 13,000 nodes, over 39,000 links, and nearly 2.3 million origin/destination (OD) pairs. In contrast, the Southern California Association of Governments' model identifies 3,200 OD pairs, over 25,000 nodes, and over 99,000 links, in addition to six distinct classifications of users. Policies and procedures related to operations vary dramatically based upon which model is selected, so this choice is of keen interest to researchers of supernetworks.

Network interactions also affect transportation supernetworks. The increasing use of electronic commerce (e-commerce), for example, reduced somewhat the number of consumers using transportation networks because they were able to conduct certain shopping at home or at work. Despite this, the escalating number of goods ordered online required transport and delivery and increased demands on the transportation network, while also greatly increasing strain on the telecommunications network.

Most transportation decisions also greatly impact the environment, as over 15 percent of global carbon dioxide (CO₂) emissions are produced by motor vehicles, as are 50 percent of nitrogen dioxide and 90 percent of carbon monoxide (CO) emissions. As more citizens of the world's developing nations embrace motor vehicles as part of their transportation networks, the sustainability of the current transportation infrastructure has been questioned. As a result, discussions regarding transportation supernetworks have had to consider the costs of pollution abatement and reduction when making plans for future development and expansion.

Conclusion

Network efficiency and performance studies must examine many aspects of transportation to assure that supernetworks operate as effectively as possible. Traffic flow involves the complex interaction between

drivers, commuters, the supply chain of goods transportation, and the interaction among numerous other supernetworks, such as those involving power, telecommunications, and other components that make up our transportation infrastructure.

Because the failure of one link can have profound effects upon the entire supernetwork's performance, identifying critical links and nodes becomes a task of paramount importance. As information has grown to be an increasingly important aspect of today's economy, the creation of new knowledge regarding the functioning and operation of transportation supernetworks has become of paramount importance.

In an era of growing international competition, some nations have chosen to focus upon those transportation supernetworks that are the most technologically advanced, acting on the belief that they require intensive development of knowledge, which is something that competitors would find difficult to replicate or underprice. As a result, transportation supernetworks are often intertwined with telecommunications supernetworks, as distance—a key barrier to transportation—can often be circumvented with telecommunications savvy. As research related to transportation supernetworks continues, additional models that make use of knowledge from different but related fields will undoubtedly gain credibility and influence.

Supply-Chain Management

A supply chain is a network that comprises every process and every party involved in the creation of goods, from before they are manufactured through to their final delivery to and purchase by the customer. Supply chains include the acquisition of materials, manufacturing, moving, and handling of goods from their source (the original supplier) to the end user or customer.

Every step in this chain involves some sort of intervention, which means that every step involves the potential to incur additional costs that the user eventually pays for at the end of the chain. Because the ability to pass goods along the supply chain most effectively will reduce the final price to the end customer—and/or increase profit for the supplier—the ability to manage the transportation actions with efficiency puts money in someone's pocket. Thus, effective supply-chain management is the ability to ensure that every step in the process is carried out as efficiently as possible, including all aspects of the transportation that occurs in the process.

The formal concepts of supply chains and supply chain management are of relatively recent origin, although in practice they have existed, albeit in a primitive form, since the 1960s. The name and formal definitions date from the 1980s but they were not widely used until the 1990s. Supply-chain management is not only now widely accepted, but it also forms the basis of an academic discipline (and degree programs with that concentration) and a lively community of organizations that seeks to define best practices and standards.

Although there has not been a great deal of activity in the study of supply chains as a serious academic discipline, that situation is gradually changing, as there has been an increase in articles addressing supply chains and their management, and scholarly books are beginning to appear, as well.

What made the introduction of supply chains and their management significant was the view of looking at an entire cycle of development and delivery that focused on an overall process with many players rather than from a single industry or participant perspective. As an overall concept, supply-chain management includes the management, oversight, communication, and planning required at every step of this complex process.

A major factor in the complexity of managing the supply chain is the potentially large number of processes: finding and getting resources, transporting them to a manufacturer or other value-add organization, the manufacture or crafting process, transportation to distributors—sometimes on an international basis—and eventual delivery to the customer. It can involve many suppliers, both of raw materials and manufactured components that make up the finished product, government agencies both domestic and international, and commercial distributors. One factor to be closely monitored by managers is that there is potential for a large number of participants, each of whom seeks to maximize its profits at its touch point, to add small extra costs along the way that will eventually add up to a large increase in the total cost to the customer.

As supply chains have become more widely used, specific applications have been developed to support the process, and third-party organizations have appeared to perform specific parts of the chain, providing managers with the ability to access support without having it as an integral part of their organizations.

The flow of materials and manufactured goods at various stages needs to be monitored using a system similar to “just-in-time” inventory because backlogs, a lack of supplies, or an interruption of the flow at some point can result in increased costs. Supply chains, to be effectively managed, must first be understood. Although different models emphasize particular aspects and have a certain degree of variance, the supply chain basically has three main components. These are the product and all processes that support its manufacture and delivery, the information that passes among all participants, and the flow of money and financial information.

Models

While there are differences in all supply chains, models have been developed to capture the salient

points of how certain models work. Some of these are developed from the perspective of the entire process, while others capture what happens before a certain point (upstream models), in the flow, or after a certain point (downstream models).

Models not only furnish a means of describing how the process flows but also provide supply-chain managers at each stage with the means to gauge progress through performance measurements. Models currently in use include the supply-chain operations reference model (SCOR), which is widely used and considered by some to be the standard means of measuring performance.

Another model is the American Productivity and Quality Center’s (APQC’s) Process Classification Framework (PCF), which is based on a high-level examination of processes. PCF is agnostic to the industry or product that is moved through the chain and is used to measure only the effectiveness of the movement of resources, products, or information. A third model is one that has been devised by the Global Supply Chain Forum, which also emphasizes all functions performed in each stage of the process, regardless of the products developed and transported to the ultimate end user.

In managing the supply-chain process, managers must consider how they will address several areas, which include how supplies and goods are actually transported and stored (that is, transportation and storage networks) and how supplies and goods will be distributed and by which modes of transportation. Additional aspects to consider are trade-offs that affect costs, especially transportation, information flows, inventory management, and financial transactions. One means to increase the effectiveness of coordination and also keep costs down is to not only coordinate activities but also create an information network in which the different parties become aware of the fact that keeping their costs as low as possible benefits everyone in the supply chain as a whole.

Globalization

One aspect of the supply chain and managing it is that in an era of increased globalization, differences among business entities that include cultural differences will probably tend to diminish. There will be a greater degree of standardization resulting in more predictability. At the same time, global supply chains will require additional security

considerations, especially in the political environment since the terrorist attacks on September 11, 2001. The United States has increased regulations in this area, and IT service management industry standards such as ISO/IEC 28000 and ISO/IEC 28001 have been published.

Another aspect of globalization is the increased pressure by nongovernmental organizations to ensure that supplies do not support the violation of good environmental standards, human rights, and fair labor practices. These, as well as other factors, may tend to complicate all aspects of the supply chain, including transportation. Also, the increased globalization will tend to complicate transportation issues, especially because of long lead times and the complex nature of international travel over long distances. Despite all of these factors, compounded by the fact that not all participants may be able to effectively deal with resultant complications, rapid improvements in information technology are beginning to mitigate these issues somewhat by increasing flow of information.

Surface Transportation Assistance Acts of 1978 and 1982

In 1978, the Surface Transportation Assistance Act was introduced in the House of Representatives by James Howard (D-NJ). HR 95-599 was signed into law (P.L. 95-599) by President Jimmy Carter on November 6, 1978. The chief purpose of the bill was to authorize \$51.4 billion in appropriations for making highway transportation safer and improving mass transit and interstate travel in both urban and rural areas.

The bill allotted funding for fiscal years 1979 through 1982, appropriating \$30.6 billion for highways, \$7.2 billion for improving highway safety, and \$13.6 billion for public transportation. It was the first time in U.S. history that Congress had authorized federal support for mass transit and highways in a single bill.

The act also amended Title I of the Federal-Aid Highway Act of 1956 by allotting federal funds amounting to no more than 70 percent of the cost of construction of new interstates and resurfacing of interstate highways that had been constructed more than five years previously. As the appropriation period authorized by the 1978 bill neared expiration, despite considerable controversy, Congress passed the Surface Transportation Assistance Act of 1982 at the urging of President Ronald Reagan.

Responding to mounting safety and environmental concerns, the Surface Transportation Assistance Act of 1982 required states to reduce highway speeds to 55 miles per hour (mph), which cut down on both fuel usage and air pollution. States that did not enforce the 55 mph federal speed limit could expect to suffer financially. Initially, federal highway funds would be cut 5 percent. If the problem exacerbated to the point that more than 70 percent of drivers within a state were speeding, the state could lose up to 70 percent of its allotted highway funding. The act also

stipulated that an environmental impact statement be submitted by fall 1983.

The 1978 Bill

Support for mass transit was an important element in the Surface Transportation Assistance Act of 1978, and Congress authorized \$15.6 million to improve mass transit. The act amended the Emergency Highway Energy Conservation Act by providing funds for carpool projects as an energy-saving measure as long as they had no negative impact on mass transit. An additional \$7.4 billion was set aside for discretionary grants to be distributed by the secretary of transportation. Grants to states included funding for programs designated for conserving motor fuels and decreasing traffic congestion. Another provision of the bill banned the operation of any state-owned service station on interstate highways.

As a result of the 1973 oil crisis brought on by the Arab oil embargo, which precipitated a steep rise in oil prices and long lines at gas pumps, many Americans turned to biking. Even though the crisis was over by 1978, biking continued to be popular because it was good exercise and was much better for the environment than burning fossil fuels. The act supported the use of bikes by appropriating \$80 million for biking projects, although Carter neglected to include those funds in his annual budgets.

Fighting back against America's dependence on foreign oil and other imports, Congress and state legislatures began passing a series of "Buy American" laws in the 1970s that placed limits on the purchase of foreign goods. Echoing the language of the first "Buy American" act passed in 1933, during the Great Depression, the Surface Transportation Act of 1978 carried a "Buy American" provision, stipulating that transit vehicles purchased by cities qualified for federal aid only if they were assembled within the United States and if no more than half of vehicle components were manufactured outside the country.

Canadian companies, which regularly provided items such as transit vehicles and highway bridge components to the United States, may have suffered more from "Buy American" laws than any other country, losing out on billions of dollars in contracts. It was estimated that Canada was prevented from making some \$50 billion on mass transit projects authorized by the Surface Transportation Act

of 1978. Some Canadian companies responded by building plants in the United States.

The 1982 Bill

The United States experienced a severe recession in the early 1980s, and Congress was forced to deal with pressure from all sides as it addressed the economy within the context of what came to be known as Reaganomics, coupled with a trend toward returning power to state and local governments.

One of the major issues facing Congress was authorizing funds for transportation, because funding allotted under the 1978 bill was set to expire. However, the Surface Transportation Act of 1982 (HR 6211) did not sail through Congress. Instead, it faced a series of filibusters from conservative senators. Some Republicans, however, were furious over the lack of support for the president's version of the bill. Many Democrats wanted funding for public works projects included in the bill, and some wanted any taxes included in the bill levied against the wealthiest Americans, rather than average consumers.

Once cloture was invoked to end the filibusters and bring the bill to the floor for debate, according to Reagan's demands, a conference committee hurriedly worked out the differences. As a means of funding highway and mass transportation projects similar to those included in the 1978 bill, the final version of the 1982 bill provided for raising \$5.5 billion in fees from highway users.

The Surface Transportation Assistance Act of 1982 also included a small bonus for consumers. The price of tires declined because the 5-cents-a-gallon excise tax shifted the tax to gasoline and diesel fuel. Since the tax was imposed at the refinery, the impact on consumers was predicted to be less noticeable. Because heavy trucks put more wear and tear on highways, the 1982 bill established an increase in usage fees, amounting to approximately \$2,200 annually, for 18-wheelers. Trucking companies benefited, however, from provisions that allowed trucks to be wider and permitted them to carry heavier loads.

The final version of the Surface Transportation Assistance Act of 1982 was harshly criticized throughout the United States. Even many conservatives were upset because the bill allowed the federal government to continue playing a major role in transportation areas that they had hoped would be turned over to states. Environmentalists were up in

arms because they felt that the bill gutted previously established environmental protection measures.

Upon signing the 1982 bill into law, Reagan noted that the bill provided funding for 4,000 miles of interstate highways that were in need of resurfacing and for 23,000 bridges that required repair or replacement. The average cost to consumers was estimated at approximately \$30 a year. Overall, passage of the bill was considered a major victory for Reagan.

water, and pipelines. The system includes many thousands of independent yet tightly connected operators of all sizes, in both the public and private sectors. The smooth operation of the U.S. surface transportation system is essential to the country's economic strength, security, and quality of life.

The Surface Transportation Board (STB) was established in January 1996 as a successor agency to the U.S. Interstate Commerce Commission (ICC) as part of the Interstate Commerce Commission Termination Act of 1995. The bill abolished the ICC and either dissolved or dispersed its responsibilities to other regulatory bodies operating under the U.S. Department of Transportation (DOT), including the STB, the Federal Motor Carrier Safety Administration, and the Bureau of Transportation Statistics.

The STB's primary goal is to provide an efficient and effective forum for the resolution of surface transportation disputes. While falling administratively under the DOT, the STB maintains decisional autonomy regarding regulation and adjudication of matters related to freight railroads, as well as certain issues involving pipeline carriers, trucking companies engaged in collective activities, moving van companies, intercity passenger buses, and water carriers engaged in trade with Alaska, Hawai'i, or noncontiguous U.S. territories or possessions. The STB also has limited regulatory authority over the National Railroad Passenger Corporation (Amtrak).

Structure of the Organization

The STB is based in Washington, D.C., and is led by three key board members who are appointed by presidential nomination and Senate confirmation. Each senior leader is placed with the organization for a designated term of service, and each executive's term is staggered to ensure consistent yet evolving leadership.

Operations of the STB are sustained by an extensive support staff and fall within six distinct offices of the organization: (1) the Office of the General Counsel provides legal advice to the board's top executives and defends the STB in court when its actions are legally challenged; (2) the Office of Economics is mainly responsible for collecting and reporting data, supporting STB decisions with economic and policy analysis, applying economic analysis to STB models and systems, and auditing Class I railroads; (3) the STB's Office of Environmental

Surface Transportation Board

Surface transportation in the United States is an extremely large and complex system that is responsible for the movement of vast numbers of passengers and huge quantities of freight via rail, roadways,

Analysis is charged with performing environmental review of actions put forth before the agency to ensure compliance with U.S. environmental policy law and also makes recommendations to the STB regarding environmental issues and implications; (4) the Office of the Managing Director handles administrative matters of the agency, such as human resources, facility management, and budgeting; (5) the Office of Proceedings is the legal office of the STB; it is focused on researching issues pending before the STB, preparing draft decisions for the public record, tabulating case votes, and recording official outcomes; and (6) the Office of Public Assistance, Governmental Affairs, and Compliance (OPAGAC), which functions as the agency's liaison with the public, managing outreach and serving as the STB's primary point of contact with the general public and with state and local governments, the media, and industry stakeholders.

The office works to provide information and address questions pertaining to the STB's regulations, procedures, and actions. The office oversees all aspects of rail operations that fall within the agency's jurisdiction to help ensure carrier compliance with statutory responsibilities by providing assistance to those seeking information and advice in that regard.

In addition, OPAGAC is home to the Rail Customer and Public Assistance Program, which offers an informal option for private-sector resolution of shipper-railroad disputes related to rates and other charges, railcar supply and service issues, damage claims, interchange problems, employee complaints, and community concerns.

The STB's efforts are supported by the Railroad-Shipper Transportation Advisory Council (RSTAC), the National Grain Car Council (NGCC), and the Rail Energy Transportation Advisory Committee (RETAC). The RSTAC advises the STB, the secretary of transportation, and Congress on railroad transportation policy issues such as railcar supply, rates, and competitive matters pertaining particularly to small shippers and small railroads. The council is made up primarily of private-sector senior executives from the railroad and rail shipping industries.

The NGCC assists the STB with problems concerning grain transportation by facilitating communication among railroads, shippers, railcar manufacturers, and the government. NGCC membership

includes representatives from railroads of all sizes, grain shippers and receivers, and private railcar owners and manufacturers. The RETAC was created in 2007 to provide the STB with guidance related to the rail transportation of energy resources such as coal, ethanol, and other biofuels. The committee's members include representatives of large and small railroads, coal producers, electric utilities, the biofuels industry, the private railcar industry, and rail labor.

Key Objectives

In regulating the U.S. railroad industry, the STB strives to accomplish and balance a number of goals in line with U.S. transportation policy. Foremost, the STB seeks to support a safe and efficient rail transportation system serving the United States and its territories and possessions. To the maximum extent possible, the board allows competition and demand for services to result in reasonable rates for transportation via rail. At the same time, it aims to protect rail shippers by maintaining reasonable rates where there is an absence of effective competition and where rail rates provide revenues that surpass the sum necessary to maintain and expand the rail system and attract capital. Another significant objective of the STB is to cultivate the continuation and expansion of a sound rail transportation system while preserving effective competition among rail carriers and with other carrier modes in order to meet the needs of the public and national security.

The STB attempts to ensure that rail carriers can earn adequate revenues to deliver and maintain consistent, efficient, and reliable transportation services, and that they can expand or enhance rail infrastructure, equipment, and technology. It also seeks to prohibit predatory pricing and practices, avoid unwarranted concentrations of market control, and prohibit unlawful discrimination.

The board works to ensure that the regulatory process is accessible and cost-effective for all affected parties and that regulatory decisions are fair and timely. It also aims to advance the environmental and energy-efficiency benefits of rail transportation and to promote energy conservation and environmentally responsible practices among rail carriers. Finally, the STB works to encourage fair wages and safe and appropriate working conditions in the railroad industry.

In its day-to-day activities, the STB adjudicates disputes and regulates interstate surface transportation in accordance with various laws pertaining to the different modes of surface transportation. The STB's general responsibilities include the oversight of companies that are involved in transportation in U.S. interstate commerce, as well as foreign commerce that takes place within the United States or between locations in the contiguous United States and points in Alaska, Hawai'i, or U.S. territories or possessions.

The surface transportation issues that generally fall under the STB's jurisdiction are railroad rate and service issues, rail restructuring transactions—including line mergers and divestitures, construction of new lines, and abandonment of existing lines—and associated labor matters, and certain rate issues tied to trucking company, moving van, and noncontiguous ocean shipping operations. Some structural, financial, and operational issues among intercity passenger bus companies and certain pipeline matters not regulated by the Federal Energy Regulatory Commission are also under the STB's jurisdiction. In performing its duties, the STB promotes substantive and procedural regulatory reform where appropriate.

A critical responsibility of the STB is to provide a forum for the efficient and effective resolution of disputes. It does so through the granting of regulatory exemptions where appropriate, the streamlining of decision-making processes and applicable regulations, and the consistent and fair application of legal and equitable principles. The STB's focused dispute resolution process facilitates appropriate market-based business transactions in the surface transportation industry. Through rulemaking and case disposition, the board strives to develop innovative ways to effectively analyze unique and complex problems affecting surface transportation, to come to fully justified decisions more rapidly, to reduce the expenses incurred with regulatory oversight, and to encourage private-sector negotiations and resolutions to problems whenever warranted.

Reauthorization

There have been several attempts over the years to reauthorize the Surface Transportation Board through legislation. One of the most recent efforts was bill S. 158, the Surface Transportation Board Reauthorization Act of 2011. The proposed

legislation was nearly identical to a 2009 bill that failed to pass. The 2011 version attempted to address rate and service concerns of rail shippers and to open the railroad industry to more competition, among other stipulations.

The Surface Transportation Board Reauthorization Act of 2011 was designed to provide comprehensive updates and improved economic oversight of the railroad transportation industry to help address long-standing competitive imbalances for shippers. The bill would have done so by facilitating increased rail competition, strengthening federal oversight, and improving access to regulatory exemptions for shippers.

Among other things, the bill would have authorized the STB to revoke class exemptions to rail carrier requirements as a way to protect rail shippers from abuse of market power. It also would have prohibited the STB from issuing to any individual other than a rail carrier a certificate to acquire a railroad line or extended or additional railroad lines that included interchange commitments or other mechanisms restricting the ability of the buyer to interchange traffic with another carrier unless the interchanges were reasonable and in the public interest.

In addition, the reauthorization act would have required that a Class I rail carrier establish, upon rail customer request, reasonable bottleneck and terminal switching rates for single-line movement or interline movement rail transportation over a bottleneck rail segment in which the carrier has market dominance. It also sought to authorize the STB to require that a Class I rail carrier, including any other rail carrier deemed appropriate, make its terminal facilities available for use by another carrier in cases where it has market dominance in a terminal area. The bill also aimed to change from discretionary to mandatory the authority of the STB to establish reasonable rail rate standards for terminal use.

Under the legislation, the STB would have been authorized to revise maximum rates of relief that it could provide to railroad shippers in certain cases of rail-rate reasonableness. Moreover, the act would have revised requirements for the approval or denial of the consolidation, merger, or acquisition of control of rail carriers, authorizing the STB to take into consideration significant effects of the transaction on public health, safety, and the environment, as

well as intercity rail passenger transportation and commuter rail passenger transportation.

The bill was not well received by large railroads, which felt that the bill was strongly pro-shipper and provided the potential for railroads to lose a significant amount of pricing power, thus damaging their ability to earn sufficient financial returns. Railroad executives argued that if the railroad industry lost the ability to earn its cost of capital, the result could generate a negative impact on capital investments needed to support traffic growth, which would likely reverse the industry's strides in the areas of rail safety and service reliability.

Many rail shippers, on the other hand, felt that the modifications to the STB's authority were overdue, citing long-standing barriers to competitive access for captive shippers. They welcomed improvement in the rate-challenge process and opportunities for relief from what they viewed to be monopoly pricing power held by the railroads.

The 2011 reauthorization legislation followed in the same path as its predecessors and failed to garner the necessary votes to pass into law. However, its content consistent with previous versions and its continued presence on legislative agendas may indicate the future direction of STB authorization and oversight within the rail segment of the U.S. surface transportation industry.

Surface Transportation Policy Project

The Surface Transportation Policy Project (STPP) is a private nonprofit organization that works to guide communities to make smarter transportation choices through consideration of how choices regarding how we get around impact the economy, environment, public health, and social equity. Working to ensure that more diverse voices and perspectives are heard when decisions are made regarding the community's transportation needs, STPP has grown to become a national force that has helped shape decisions related to spending, approval of projects, social justice priorities, and the synergy between transportation choices and the communities these projects serve. Working with other groups that advocate greater opportunities for and rights of bikers, joggers, walkers, and others, the STPP has been able to shape decisions made in a variety of settings across the United States.

Background

Founded in 1990, the STPP's formation coincided with a growing national interest in how transportation shaped and affected communities. After nearly 40 years of uninterrupted growth in the U.S. interstate highway system and commercial aviation industry, both of these modes of transportation were nearing the saturation point. As a result, conversations regarding transportation planning and policy took on a new and significant tenor.

Rather than focusing upon how to plan, implement, or fund a given mode of transportation—such as a highway, an air terminal, or a light rail system—planners examined how different forms of transportation could be coordinated to provide communities with the best combination of services possible. The STPP was formed to ensure that these discussions considered how transportation affected the economy, the environment, public health, and social justice. Because the timing was right for such a discussion, although the STPP was a new organization, it quickly became a major player in debates regarding intermodal transportation policy and planning.

STPP played a role in the U.S. Congress' passing the Intermodal Surface Transportation Efficiency Act (ISTEA) in 1991. As the first transportation legislation to follow the completion of the

interstate highway system, ISTEA (pronounced “ice tea”) initiated collaborative planning requirements that necessitated the input of municipal, local, state, and federal authorities, as well as that of the general public. ISTEA, which expired in 1997, focused upon the creation of high-priority corridors that became part of the national highway system.

Unlike its predecessors, ISTEA provided funding for automobile, rail, and other forms of transportation. For example, ISTEA provided planning support and funding for Minnesota’s Cedar Lake Trail, the first federally funded nonmotorized trail, sometimes referred to as the first “bicycle freeway.” ISTEA also funded 80 high-priority corridors that added to the national highway system, augmenting existing routes in areas of high need. ISTEA also envisioned five high-speed rail corridors, one in the Midwest, one in the southeast, one in Florida, one in California, and one in the Pacific Northwest. Although a great deal of planning and study went into these high-speed rail corridors, funding did not follow, and other than some money allocated for improving grade crossings, nothing came of these plans until \$8 billion was allocated for this in 2009 as part of the American Recovery and Reinvestment Act. Despite this, ISTEA proved widely influential and affected subsequent legislation, such as the Transportation Equity Act for the 21st Century of 1998 (MAP-21) and the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users, (SAFETEA-LU) in 2005.

Based in Washington, D.C., the STPP has continued to advocate transportation changes on the national, state, and local levels. The STPP concentrates on four broad areas: enhancing the economy, improving public health, promoting social equity, and protecting the environment. As a 501(c)(3) nonprofit, STPP relies on funding from a variety of individual donors and foundations that share its goals. Local and national foundations that support STPP include the Ford Foundation, the John D. & Catherine T. MacArthur Foundation, the Robert Wood Johnson Foundation, the Rockefeller Foundation, and the Surdna Foundation.

In the two decades since its founding, STPP has established several basic principles it pursues across the United States. It consistently seeks money for bicycle, pedestrian, and transit infrastructure, believing that these forms of transportation best reduce society’s carbon footprint while

The Cedar Lake Trail, which is sometimes called the first “bicycle freeway,” in downtown Minneapolis, Minnesota, in July 2011. It was the first federally funded nonmotorized trail and was made possible by the Intermodal Surface Transportation Efficiency Act.

also providing the most positive return for each dollar spent. STPP presses for repairing and rebuilding existing roadways before new road funding is approved, based on the belief that the neglect of certain stretches of thoroughfares disproportionately affects low-income individuals and communities.

As a reliable advocate for the revitalization of the National Railroad Passenger Corporation (Amtrak) and America’s various freight carriers, STPP favors the economic necessity of maintaining and reviving the aging rail infrastructure of the United States. A stalwart advocate for reducing urban sprawl, the STPP uses a variety of tools to achieve its goals. It produces a variety of research reports, fact sheets, and other materials to assist the general public in better understanding the issues. Its professionals also monitor how well federal and local transportation systems perform, holding their leaders accountable for an acceptable level of performance. As a result of these efforts, STPP continues to play a significant role in shaping American transportation policy, planning, and implementation.

Policy Initiatives of STPP

For its primary areas of concentration, STPP works to raise awareness of and create consensus for sustainable transportation policy. To support its goals, STPP works to address popularly held misconceptions and concerns that might interfere with the pursuit of the policies it favors. To that end, STPP both funds research that helps it to build the case for government leaders and private businesses pursuing sustainable transportation policies, and creates materials that make its position clear, cogent, and compelling to interested members of the public. This course of action has proven highly successful, and the decision to focus on the economic and health benefits of sustainable transportation policy has proven a popular way to rebut opposition.

Discussions regarding the economic impact of sustainable transportation policies have historically focused upon the increased costs following such a path causes. To rebut this, STPP has instead concentrated on the economic benefits that stem from an efficient and reliable transportation system. STPP directly addresses the reality that business owners are the primary source of tax revenue for most communities. In this role, businesses also suffer the most from the inefficiencies caused by inadequate infrastructure—delivery delays, lost employee work time, and stressed and unhappy customers.

Because unpleasant commutes reduce the available workforce, STPP emphasizes how a failure to invest in sustainable and efficient transportation systems ultimately drives up business owners' costs. Time workers spend behind the wheel of their automobiles or searching for parking is often time that is lost from the workday. STPP also emphasizes that such delays cause a tremendous amount of wasted gasoline, as cars that idle on the freeway use imported resources and increase pollution. Delays in delivery times caused by clogged transportation systems dramatically reduce the economic benefits of just-in-time inventory systems that have been implemented to increase profits. As STPP focuses on the economic costs of an unreliable and inefficient transportation system, it reduces resistance to the increased expenditures necessary to implement sustainable transportation policies.

Similarly, STPP leverages the common interest in providing a secure and healthy transportation system that will benefit all members of society. Focusing on the primary and secondary risks promoted by a

car-based transportation system, STPP addresses the risks caused by increased pollution and the crowding such a system causes, as well as the unhealthy sedentary practices of the public that are encouraged by a reliance on automobile transportation.

By demonstrating a positive correlation between a reduction in the number of children's trips made on foot with an increase in the number of overweight and obese youth, STPP again draws attention to the unintended and hidden costs associated with transportation policies that ignore the needs for more healthy behaviors. When the United States spends \$600 billion annually as a result of this inactivity, investment in transportation systems that encourage more movement begin to look less expensive. Motor vehicles are also responsible for increased air pollution, which in turn leads to increased absenteeism from school and work, emergency room visits, and death. By examining the health costs associated with vehicle emissions, STPP effectively has built support for transportation systems that encourage walking and bicycles.

Addressing social equity concerns caused by sustainable transportation policies, or a lack thereof, the STPP has examined the disproportionate harm suffered by Americans from low-income backgrounds or those who are persons of color. Access to good jobs, education, and training, as well as necessary services and commercial opportunities, is reduced for these groups when inadequate money is invested in sustainable transportation systems.

Historically, the homes of ethnic minorities were disproportionately destroyed as the federal government built and expanded the interstate freeway system, often in the name of "urban renewal." Today, high-polluting transportation centers, such as diesel bus centers, are much more likely to be located in minority-majority neighborhoods and asthma rates among children of color have soared as a result.

The distance of these neighborhoods from jobs makes employment opportunities less likely and the increased costs of transportation reduce the likelihood of wealth accumulation for many of America's poor, especially those in rural and urban areas. Indeed, the poorest 20 percent of Americans spend over 40 percent of their income for the purchase, maintenance, and operation of automobiles. By demonstrating that increased spending for sustainable transportation systems would reduce costs

for welfare, food stamps, medical care, and other expenses, STPP again builds the case for increased spending on the infrastructure that would reduce dependence on the automobile.

Finally, STPP examines the link between the current transportation in the United States and the environmental degradation that is occurring globally. Exploring this popular issue, STPP shows how over 125 million Americans live in areas with unacceptable levels of air pollution, a condition that the U.S. Environmental Protection Agency (EPA) estimates leads to over 60,000 premature deaths per year. Additionally, many other health conditions—such as heart disease, asthma, and other respiratory diseases—are exacerbated by air pollution, with those from low-income communities suffering most severely.

The effects of air pollution are not limited to humans, as the EPA also estimates that smog and acid rain kill over \$3 billion worth of crops each year. Additionally, paved roads greatly increase water pollution, allowing benzene, soot, additive methyl tertiary butyl ether (MTBE), and other contaminants to enter the groundwater. High energy consumption and increased animal road kill are also directly attributable to our current transportation policies. STPP emphasizes these ills as a way of increasing support for more sustainable transportation policies and spending.

Conclusion

For over two decades, STPP has worked to build consciousness regarding the harm the automobile-centered transportation policies pursued by the United States over the past seven decades have caused, and has worked to build coalitions to support a change to more environmentally sustainable practices. By emphasizing the economic, health, social equity, and environmental problems with our current course of action, STPP has been successful in getting increased attention paid to possible alternatives. While a great deal remains to be done, the changes effected over its existence have proven to be significant, substantial, and lasting. As more political leaders from a variety of backgrounds become open to sustainable transportation policy, STPP's influence should continue to grow.

Surface Transportation Program

The Surface Transportation Program (STP) is a program providing federal funding for a wide range of transportation projects, and is historically the largest and most flexible federal highway program. The Surface Transportation Program is one of the four core federal surface transportation programs funded by the Moving Ahead for Progress in the 21st Century Act (MAP-21), which was signed into law in July 2012. After several years delay, MAP-21 succeeded the previous surface transportation funding bill, the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU), which had expired in 2009.

Under MAP-21, most federal surface transportation funding is disbursed through four consolidated programs: the Highway Safety Improvement Program, the Congestion Mitigation and Air Quality (CMAQ) program, the National Highway

Performance Program, and the Surface Transportation Program. The STP distributes funds to a wide range of transportation projects. Projects that can apply for funding may be located on any highway receiving federal aid, which includes the entire National Highway System, any bridge on any public highway, and intracity or intercity bus terminals and facilities. Further, they must be developed consistently with the required Regional Transportation Plan, conform with the Clean Air Act and relevant amendments and other environmental requirements created by law, and abide by Title 23 and/or Title 49 of the U.S. Code.

Project types as defined in Title 23, Chapter 1, Section 133 of the U.S. Code include transit capital projects that provide intercity bus service; highway and bridge projects, including the construction of new projects and the rehabilitation, restoration, resurfacing, and reconstruction of existing projects; transportation safety infrastructure projects, hazard mitigation, railway-highway grade crossing elimination; research and development programs; transportation planning programs; transportation management systems; wetlands and natural habitat mitigation; environmental restoration and pollution abatement programs; and any environmental mitigation and right-of-way construction associated with the above.

Common preventive maintenance programs also funded include seal coats, corrective pavement grinding, drainage system repair, and rehabilitation of joint and shoulders, but not spot applications, which apply for separate normal maintenance funds.

The STP originally included carpool, bicycle, and pedestrian projects, which were expanded under SAFETEA-LU and have been reduced and grouped together as Transportation Alternatives under MAP-21. MAP-21 also added \$5 billion in new responsibilities to the Surface Transportation Program, while increasing program funding by \$1.2 billion, to \$10 billion. MAP-21 folded into the STP the previously separate programs Equity Bonus, Appalachian Development Highway System, and Border Infrastructure Program. Equity Bonus had previously been known as Minimum Guarantee and was designed to return at least 92.5 percent of gas tax revenue to states, a political measure to make the federal gas tax (the rate of which has remained unchanged since 1993) more palatable.

Under MAP-21, the original Equity Bonus program is replaced by a formula to base state apportionments of highway formula funds on each state's share of 2012 apportionments. The Appalachian Development Highway System is a system of roadways and corridors throughout the 13 states of the Appalachian region. MAP-21 left funding for this program unchanged insofar as previously allocated funds remained available, but no new funding was added.

STP covers up to 80 percent of the total cost of an approved project, with state or local governments providing the remaining funds. States are also required to allot an amount equal to 15 percent of the funds they received from the 2009 Highway Bridge Program to fix bridges that are not on the federal highway system. This is in addition to the STP money states are required to distribute to metropolitan areas.

This is the first time STP has assumed responsibility for the 460,000 federal-aid bridges outside the National Highway System, which previously were eligible for funds under a Highway Bridge program eliminated by MAP-21. While MAP-21 reduced the number of bridges eligible for federal funding for repairs, it also failed to increase STP's funding to account for those bridges that retained eligibility.

In an age in which economic policies favoring strong states' rights over strong federalism have been revived by a staunchly conservative Republican Party, the existence of the STP has been called into question. In theory, the federal role could be reduced or eliminated entirely, with both the gas tax and the responsibility of maintaining highways transferred to the individual states. The best argument against this is that the federal gas tax already exists, while the political consequences of 50 separate battles to enact a new gas tax in the states could be severe enough that highways in at least some states would surely go unfunded for a time.

The major rationale for the STP is that there is a compelling national interest in maintaining the existence of a functioning and healthy intercity transportation system, which is far more critical to the nation's health today than it was a century ago, when federal highway aid was first instituted. The federal government is able, indeed is expected, to engage with concerns that may seem abstracted or too long term minded to be handled at the state level, such as environmental impact concerns, or

the long-term need to increase mass transit coverage and ridership in order to prevent unmanageable traffic and undesirable emissions levels.

Further, there are a significant number of transportation projects that straddle multiple states or other jurisdictions. If the responsibility for such projects were left to the individual states, they might be indefinitely postponed while various jurisdictions battled over the allocation of responsibility.

In New England, for example, southern New Hampshire serves as a bedroom community for Boston, Massachusetts, and also provides sales-tax-free shopping for the greater metropolitan area, so a program to extend Massachusetts Bay Transportation Authority (MBTA) service from Boston to southern New Hampshire communities has the enthusiastic support of both states but is continually stalled by disagreements over which jurisdiction should provide what level of funding support.

MAP-21 also changed the process of environmental review for STP projects by adding to the number of exempted project types. Environmental review in the form of environmental impact studies and the production of environmental impact statements, combined with the opportunity for the public to become engaged with the planning process, has been a cornerstone of the federal government since 1969.

The new process exempts projects that involve repairs or new construction in response to a natural disaster, projects on sites already home to transportation projects, and projects primarily federally funded but costing \$5 million or less. For those projects not exempt, the federal agency conducting the review is given a four-year deadline—less than half of the average length of time of a review—to complete the process or face a fine, the first time federal agencies have faced the possibility of fines for failing to complete an environmental review in a given period of time. Opponents of the new process have argued that it will lead to projects being rejected rather than risk a lengthy review that could incur a fine.

Sustainable Transportation

The transportation system is the backbone of economic and social progress and the means by which humans access goods and services and connect with one another. Yet, as the scale of transportation activities has grown worldwide, so too have the negative environmental, social, and economic impacts that relate to the construction and maintenance of transportation infrastructure, and the operation or use of the different transportation modes.

The concept of sustainable transportation emerged in response to these concerns as part of the broader notion of sustainable development. Given the transportation sector's significant contribution to global challenges such as climate change, it is often said that sustainable development cannot be achieved without sustainable transportation.

What Is "Sustainable Transportation?"

"Sustainable transportation" generally refers to transportation that is compatible with broader environmental, social, and economic goals. Transportation is one of many sectors that either contributes to or negatively impacts sustainable development. Therefore, it is essential to first understand the holistic principles, criteria, and policies of sustainability before considering how they can be applied to the specific context of the transportation sector.

Similarly, when focusing on sustainable transportation, it is important to recognize the broader holistic principles and issues.

The concept of sustainable development emerged over the past several decades, mainly driven by the actions of the United Nations. A particular landmark was the 1986 report *Our Common Future*, published by the World Commission on Environment and Development (WCED), also known as the Brundtland Commission, after its chairperson Gro Harlem Brundtland. This report presented what has become the most cited definition of sustainable development:

Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs. It contains within it two key concepts: (1) the concept of “needs,” in particular the essential needs of the world’s poor, to which overriding priority should be given; and (2) the idea of limitations imposed by the state of technology and social organization on the environment’s ability to meet present and future needs.

Our Common Future thus defined the major objective of development as the satisfaction of human needs and aspirations while giving equal consideration to present and future needs, and taking special note of the environmental limits for satisfying those needs. It also described sustainable development as a process of change, rather than an end goal/state. The 1992 UN Conference on Environment and Development (known as the Rio conference) was another watershed event. Since the Rio conference, it has become standard to refer to three dimensions, or pillars, of sustainability (that is, economic, environmental, and social), which all should be taken into account if development is to become sustainable.

These three dimensions are also sometimes referred to as the “triple bottom line.” The Rio conference also led to the adoption of the Rio Declaration on Environment and Development, which codified a wider set of principles of sustainable development (such as the precautionary and polluter-pays principles, as well as more process-related principles such as the need for cooperation, stakeholder participation, and integrated thinking), and Agenda 21, often referred to as a blueprint for sustainable development. Agenda

21 provides numerous directions for action and focuses on several sectors, including transportation (specifically, urban planning) and energy. The conference also adopted the United Nation’s Climate Change Convention.

However, it was not until the Rio+20 event in 2012 that the significance of transportation for sustainable development was fully recognized. In the conference’s closing document, heads of state and governments agreed that

... transportation and mobility are central to sustainable development. Sustainable transportation can enhance economic growth and improve accessibility. Sustainable transport achieves better integration of the economy while respecting the environment.

The development of transportation policies that are truly consistent with sustainable development is challenging. The introduction of biofuel blends into diesel is one such example. While this may reduce emissions of carbon dioxide, it may distort agricultural markets or cause habitat loss. It is also clear that context matters and developing countries, for example, may need substantial expansion of infrastructure to build sustainable economies, whereas some developed countries may need to transform, or even contract, their systems in response to factors such as climate change. Given these factors, some scholars have argued that crafting a meaningful definition of sustainable transportation is impossible, or even that the very notion of sustainable transportation wrongly suggests that transportation could ever become a sustainable activity in itself. Others, however, including many governments, agencies, and international institutions, find that transportation is too important for sustainability to be left without clear conceptual guidance in this regard.

This latter contention has spawned a variety of concepts, such as sustainable transportation systems, sustainable mobility, sustainable infrastructure, sustainable road management, and so forth. Such concepts become influential particularly when they form the basis for objectives and strategies adopted at local, national, or international policy levels, or for indicators to track progress toward—or away from—sustainability.

Planners and stakeholders with an even more practical view on sustainability tend to focus

directly on ways to promote certain modes of transportation perceived to be inherently sustainable, such as walking, bicycling, public transportation, car sharing, eco-driving, or the use of renewable propulsion sources. However, more cautious or subtle approaches refer to sustainable transportation more as a vision, a paradigm, or a set of principles, rather than something that could be straightforwardly defined or singled out.

Normative, Analytic, and Strategic Debates

It is useful to distinguish three interrelated strands in the sustainable development debates that have strongly influenced how sustainability has been applied to the transportation context.

The normative strand addresses the fundamental ethical principles of sustainability and development, such as those introduced by the WCED and the Rio Declaration. Different normative assumptions may be reflected in the emphasis placed on certain principles versus others. A case in point is whether the three pillars of sustainability are considered to be of equal importance, or if some sort of hierarchy is assumed, whereby either the protection of environmental systems, equitable economic development, or integrated participatory decision making is considered to be the most fundamental aspect of sustainability.

The analytic strand relies on science to determine whether an action is sustainable. In the analytic perspective, an action is unsustainable if it cannot be continued in or near perpetuity. Specific attention is therefore given to identifying system states, how they change over time, and the processes that are undermining sustainability. Natural sciences and economics in particular provide a wide range of theories and methods to help determine limits to sustainability impacts. These have helped define air quality thresholds that are applied in cities and climate change targets. Concepts such as ecosystem services, carrying capacity, critical loads, and natural capital are key examples. Analytic tools can also help define and prioritize cost-effective approaches to introducing policies to address problems.

The strategic strand relates to the system of governance—from the local to the global level—that promotes change toward sustainability through policies, programs, and initiatives. From this perspective, sustainability is more of a process where actions are continually assessed against identified sustainability

principles, policy goals, and scientific evidence to determine whether laws, policies, programs, or institutional changes are promoting the desired change.

The breadth of the issues that need to be considered (from access to local health care through electrification of the vehicle fleet to global supply-chain security) pose real challenges in drawing boundaries around the scope and responsibility of different actors in the governance mix and where transport finishes and other sectors begin. This can further complicate agreement on and the development of consistent approaches to sustainable transportation. Both the normative and analytic dimensions play important roles in the strategic dimension, but other factors such as framing and stakeholder dynamics are also essential in this context.

Weak Versus Strong Sustainability

Even if common sustainability principles can be agreed upon, there are different and even contrasting interpretations of how to operationalize sustainable development. One example is the two divergent ideas of weak versus strong sustainability. Both concepts are based on the capital model of development, according to which sustainability requires the overall stock of natural social, human, manufactured, and financial capital to be maintained.

Within this context, weak sustainability is based on the notion that natural capital (i.e., nonrenewable and renewable resources and ecosystem services) can be substituted or replaced by other capital, such as manufactured capital or technology. This implies existing resources can be consumed as long as the revenues generated from this activity are invested in a way that enables future generations to be as well off (overall) as the current one.

In contrast, strong sustainability is based on the notion that the economy must operate within the carrying capacity of the environment. The strong sustainability model rejects the idea that the most fundamental services provided by nature can be replaced by manufactured capital (for example, a water treatment plant cannot replace all of the services provided by a wetland, which also provides a habitat for wildlife, aesthetic value, and so forth).

Herman Daly developed a basic set of rules for decision making from this perspective: (1) the harvesting rates of renewable resources should not exceed the rates at which they can be regenerated, (2) nonrenewable resources should not be used

faster than renewable substitutes can be created, and (3) pollution should not exceed the renewable assimilative capacity of the environment. It is useful to observe how these contrasting views are reflected in the discourse of sustainable transportation.

Definitions and Principles

Concepts and definitions of sustainability in transportation have arisen in a variety of contexts and through different pathways. Two basic approaches to conceptualizing the idea can be distinguished: the sustainability-centered approach and the transportation-centered approach. The former springs from the international arena, where transportation is considered to be one of many sectors contributing to—or hampering—sustainable development. The focus here is on framing transportation within key normative, analytic, or strategic strands of the notion of overall sustainability. The transportation-centered approach has emerged from the community of transportation planners, engineers, policy makers, and researchers. From this perspective, transportation systems and services are the center of attention, and issues such as climate change, environmental protection, livable communities, energy efficiency, and economic development become subthemes within the concept of sustainable transportation. The majority of literature on sustainable transportation has been written from this second perspective. Both perspectives have merits and limitations in the way they balance the holistic versus specific conundrum of sustainable transportation.

The sustainability-centered perspective is important since it defines the boundaries (the ecological limits or natural carrying capacity) within which all sectors must collectively operate. It also highlights the need to establish a national framework to address sustainable development that can encourage sectors to coordinate and integrate their activities. The holistic perspective of development is where debates around the weak versus strong form of sustainability (or sustainable transportation) are best situated. In contrast, the transportation-centered view is important since it provides understanding of the dynamics of the transportation systems and connects sustainability to sector-specific transportation policies and programs, balancing social, economic, and environmental concerns.

An example based in the former perspective is the following definition of “environmentally

sustainable transport” proposed by the Organisation for Economic Co-operation and Development (OECD). Inspired by strong sustainability principles, the OECD defined sustainable transport as the following:

. . . transport that does not endanger public health or ecosystems and meets needs for access consistent with (a) use of renewable resources below their rates of regeneration, and (b) use of nonrenewable resources below the rates of development of renewable substitutes.

In contrast, a more transportation-centered definition of sustainable mobility proposed by the World Business Council for Sustainable Development is the following:

The ability to meet the needs of society to move freely, gain access, communicate, trade and establish relationships without sacrificing other essential human or ecological values today or in the future.

The most widely cited definition of sustainable transportation was crafted by Canadian and European experts and adopted in 2001 as the European Union’s official policy. It seeks to combine elements from both the sustainability- and transportation-centered perspectives. It defines the following as a sustainable transport system:

1. Allows the basic access and development needs of individuals, companies, and societies to be met safely and in a manner consistent with human and ecosystem health, and promotes equity within and between successive generations
2. Is affordable, operates fairly and efficiently, offers choice of transport mode, and supports a competitive economy, as well as balanced regional development
3. Limits emissions and waste within the planet’s ability to absorb them, uses renewable resources at or below their rates of generation, and, uses nonrenewable resources at or below the rates of development of renewable substitutes while minimizing the impact on the use of land and the generation of noise

Table 1 Principles of sustainable transportation

Environment	Society/Equity	Economy	Governance
Adopt • A precautionary and preventative approach to decision making Avoid • Irreversible impacts • Global climate change • Pollution Encourage • Remanufacturing/reuse and recycling of transportation vehicles and equipment Ensure • The proper disposal of transportation-related toxic materials and waste Protect • Habitats/ecosystems and operate within their assimilative and regenerative capacities • Biodiversity • Environmental aesthetics	Enhance • Safety • Human health • Social well-being/quality of life Promote • Equity/distributional fairness • Access and choice • Environmental justice • Individual and community responsibility • Meaningful employment in the transportation sector	Ensure • Transportation services are affordable • Transportation is cost-effective • Natural and financial resources are used efficiently • Negative social and environmental costs are internalized—that is, the polluter-pays principle Support • Trade and business activity that enhances productiveness and contributes to development • Economic development	Encourage • Technological innovation Ensure • Transparency and accountability • Public and stakeholder participation Establish • Goals and performance objectives Support • Comprehensive and long-term planning • Interagency and international cooperation • The integration and co-optimization of policy

Source: Gudmundsson, H., R. P. Hall, G. Marsden, and J. Zietsman. *Sustainability in Transportation: Making it Count*. Berlin: Springer and Samfundslitteratur, 2013.

By its sheer length and complexity, this definition demonstrates the challenges of condensing the notion of sustainable transportation into a single statement. While it captures many aspects, it does not provide much guidance for action.

Table 1 provides a summary of basic principles that arguably provide a more flexible and operational conceptual underpinning for sustainable transportation. The fourth column that is not normally included in definitions of sustainable

transportation is the role of (national, regional, and local) governance. Several principles are shown that could be used to guide government action to support the objectives of sustainable transportation and sustainable development.

Many of the principles in Table 1 are not new and have been long understood as important by transportation professionals. However, the recognition that all of these principles could be important to decision making poses new challenges to the

breadth of the transportation planning and service delivery task.

Similarly, important drivers such as rapid technological change and increases in personal wealth can shorten the time period available to address emerging problems/externalities. For example, the rapid motorization of much of the developing world produces challenges on new scales that will require innovative and urgent action to resolve. The interest in identifying and implementing sustainable transportation solutions has perhaps never been greater.

The pathways toward these solutions are likely to be found in a broad range of instruments, such as technological innovation, investment (particularly in mass transit), regulation, taxation, user charging/fee rebates (“feebates”), direct marketing, and capitalizing on the potential for active travel. If the solutions are to be effectively integrated, there is evidence that broader strategic approaches such as multimodal or integrated planning and sustainable urban mobility plans will be important tools to bring together the actions of a range of different bodies charged with delivering transportation. Clear principles, goals, and monitoring frameworks can facilitate the ways in which different actors understand their role.

While there is no established discipline of sustainable transportation analysis, it represents a rapidly developing field of inquiry where transportation systems, behaviors, and policies are challenged from a comprehensive perspective with a particular view to environmental impacts and limits.

Tax Increment Financing Districts

A tax increment financing district (TIF) is a distinct geographical area within a city or town in which an economic development policy known as tax increment financing is implemented, generally in a blighted area, as a means of funding public infrastructure improvements that will foster real property development and real development. Tax increment financing allows the municipality to freeze the taxable property value for the specified area for a limited time, and revenues from subsequent increases in property value are placed into a fund that is used to finance improvements in the district, which could include land acquisition, site development, property rehabilitation, transportation improvements and investments, water and sewer expansion, and building expansion.

First used as a funding technique in California in 1952, the rapid growth of TIFs began in the early 1980s when local governments were confronted with cuts in federal funds for economic development and infrastructure projects. By 2011, TIF laws existed in 49 states and the District of Columbia, although regulations varied greatly across states. Controversy accompanied the increase. Critics charged that TIFs were ineffective; unfair to other taxing authorities, such as school districts;

and susceptible to misuse. In 2011, the California Supreme Court upheld Governor Jerry Brown's elimination of redevelopment agencies and TIFs, but the battle over TIFs continues in California and many other states.

History and Structure

Urban redevelopment was a hot-button issue during the 1940s. From 1941 to 1948, legislatures in 25 states passed urban redevelopment acts to give local governments tools to address urban problems such as blight, degraded buildings, and a lack of affordable housing. Congress passed the Housing Act of 1949 as part of President Harry Truman's Fair Deal. Among other provisions, the act authorized \$1 billion in loans to help cities acquire slums and blighted land for public or private redevelopment. It also allotted \$100 million every year for five years for grants to cover two-thirds of the difference between the cost of slum land and its reuse value.

California passed its Community Redevelopment Act in 1945, allowing the state to create redevelopment agencies (RDAs). Eager for their share of the federal loans and grants, California voters approved a constitutional amendment in 1952 that allowed RDAs to use tax increment financing to fund their redevelopment plans, thus generating local revenues that could be used to match federal funds for urban redevelopment. TIFs did not spread quickly beyond California, with only six additional states passing

enabling legislation by 1970. Oregon made TIFs legal in 1960, and Florida granted local governments the right to set up TIFs in 1969. Most states took a more conservative approach to implementation.

For those states that did adopt appropriate legislation, tax increment financing allowed redevelopment agencies to capture increased property tax revenue in their project areas to fund their activities. Although policies and procedures differed somewhat from state to state, the basic process was the same.

The first step required a local government, under the authority of an RDA, to identify a blighted area within its boundaries where redevelopment was feasible and declare the area a TIF with a limited life span, typically 20 years, although the period could be as long as 50 years. The redevelopment initiatives are controlled by the city, either directly or via an economic development agency that is typically under municipal control. They may be funded on a cash basis or, more often, by issuance of bonds.

After determining the existing tax base of the TIF for a specified year, the agency estimates the local tax revenue growth that would occur within the TIF as a result of targeted improvements. The assessed valuation of property within the TIF is then frozen at the base year. This assessed value of the property determines the taxes that will belong to all the taxing authorities (county, school district, fire district, etc.) within the TIF.

All the assessed value above the base value—a portion referred to as the incremental assessed value—belongs to the TIF, and no other taxing authority has a legal claim on this value, unless specified by law. Capital projects that will encourage redevelopment and leverage private investment within a TIF are constructed with debt that is paid off by the increased property taxes received as a result of the improvements.

When the designated life span of the TIF expires, all the tax revenues from both the base assessed value and incremental assessed values revert to the general fund, thus increasing tax revenues that benefit other taxing authorities or reduce tax rates for taxpayers. The rationale underlying TIFs is simple: large public projects increase the value of nearby private property, thus increasing tax revenues. If a public agency funds a redevelopment or infrastructure improvement project, the money to repay the debt comes from the incremental increase in tax payments. The actual growth that individual

TIFs produce can vary considerably, even within the same state or same city. However, even modest growth can be a wise investment if the growth would not have occurred in the absence of the TIF.

For two decades, TIFs were in limited use, but that practice changed in the 1970s. Federal funds for urban renewal agencies were cut, but the need for infrastructure improvements and economic development were still pressing. In 1978, California's Proposition 13, which cut property taxes by 30 percent and capped the rate of increase for the future, became the law noticed round the country as tax revolt at state and local levels spread.

Within five years after Proposition 13 was passed, nearly half the states had adopted some measure to limit the government's ability to raise taxes. Since redevelopment agencies were separate legal entities and not governed by the new tax laws, the popularity of TIFs increased significantly in the wake of these changes. Many states also used TIFs to provide public financing, tax incentives, and regulatory relief to businesses they were courting for location or relocation within their borders. By 1984, 28 states allowed the use of TIFs. By 1987, 33 states had adopted legislation that authorized TIFs, and by 1992, the number had reached 44.

TIFs were originally justified as a means by which local communities could self-finance the redevelopment of blighted urban areas. With the proliferation of TIFs, they were used in both blighted and non-blighted areas for a range of projects associated with redevelopment, development, or related physical infrastructure improvements, such as elementary and secondary schools, roads, bridges, parking facilities, recreational facilities, water and wastewater facilities, and electrical power plants.

To prevent abuse of TIFs, about 20 states made a legal requirement for authorizing a district (the "but-for" determination), that the anticipated growth in tax revenues would not happen but for the capital projects funded by the TIF. Even in those states with no legal requirement, political pressure existed to address concerns that the payment of TIF project debt will come from a new source of revenue rather than revenues that would have been created without the district.

Benefits

The widespread and long-standing use of TIFs as an economic development tool attests to their

effectiveness and flexibility. Proponents argue that TIFs prove their effectiveness in a variety of ways. TIFs attract businesses and industries to locate or expand within the targeted area, resulting in increases in jobs, wages, and property value and taxes. TIFs have not only financed successful commercial and industrial projects but they have also built affordable housing, helped in the revitalization of low-income and moderate-income neighborhoods, and addressed environmental problems, such as redeveloping brownfields and properties that have been abandoned or underutilized because of actual or perceived contamination to the environment.

Once the blighted area is revitalized, the economic growth created may reach beyond the district. Economic and population growth associated with the TIF may generate greater revenue sources for the local government through increases in local income taxes, sales taxes, and motor vehicle excise taxes. For example, there is empirical evidence that TIF programs in Michigan accelerated property value growth, and TIF programs in Indiana raised property values and employment levels.

TIFs have also proven to be a broadly useful development tool. Communities across a wide range of socioeconomic characteristics have used them successfully to deal with problems as varied as tax and expenditure limitations, infrastructure demands from population growth, and declines in intergovernmental aid. TIFs have unified normally antagonistic groups (including developers, neighborhood groups, and local government officials) to form an effective public-private partnership that may benefit redevelopment within the larger area.

One of the most attractive qualities of TIFs is their self-financing apparatus. They are able to tackle important projects that have significant economic impact without increasing taxes or requiring other direct public investment. TIF projects are funded through the increased tax revenues that the projects themselves generate rather than requiring subsidies from other overlapping governments.

If the project requires that bonds be issued, the municipality is able to issue tax-exempt bonds with low interest rates that will be paid from the incremental lift rather than from the general funds. After the bonds have been paid, the local government and local nonmunicipal districts, such as school districts, will benefit from increased taxes from the revitalized area.

Flexibility is another primary strength of TIFs. They can be authorized in areas that meet the legal requirements of the particular state, and they can be applied to any financially feasible project, regardless of size. They can also be inaugurated at any time a development opportunity is identified. Perhaps most important, they are flexible enough to be used in combination with other financial incentives to retain and expand businesses or attract new business to the community. Local control allows TIFs to avoid the bureaucratic delays and seemingly infinite red tape too often associated with intergovernmental revenue.

Transportation Improvements

State laws determine the kinds of TIF projects that can be authorized. From the earliest TIFs, infrastructure improvements, which can include improvements to roads and highways, have been part of the package. However, as cash-strapped cities needed funding for vital transit improvements and extensions, more TIFs were employed specifically to fund transit projects.

TIFs have been used to fund wholly, or in conjunction with other programs, projects as varied as the construction of streetcar lines in Seattle, Tampa, and Portland to Atlanta's eight-lane, yellow 17th Street Bridge over the I-75/85 Downtown Connector, part of the city's extensive TIF-funded Atlantic Station Steel Mill Redevelopment Project.

Illinois allows TIF funds to be applied to infrastructure and transit projects. Chicago, a city with almost 30 percent of its area designated as TIF-defined districts, funded three transportation projects in the central city in this manner. These projects include the Randolph/Washington station, the Dearborn subway, and various transit projects within central Chicago's Loop. The city allocated \$42.4 million in TIF revenue to the Randolph/Washington station. In the capital improvements element, \$13.5 million of TIF revenue has been funded for this project. The Randolph/Washington station project was implemented through an intergovernmental agreement on infrastructure expenses, such as track and tunnel connection.

Oregon was within the first group of states to make TIFs legal. Portland's Gateway community was designated as a TIF in June 2001. The plan reflects a \$164 million budget spanning over 20 years. Projects include a new transit center, a new

Atlantic Station is a neighborhood in midtown Atlanta, Georgia, consisting of 138 acres located on the former site of the Atlantic Steel mill. The redevelopment of the land was financed not only by private investments but also by a special tax district, which helped pay for public utilities such as streets, sidewalks, and sewers. The yellow 17th Street Bridge was constructed over the I-75/85 Downtown Connector expressway and is the primary access to and through Atlantic Station. The bridge is an enormous eight lanes wide.

medical building, low- and moderate-income housing, realignment of dangerous intersections, and wider sidewalks, increased pedestrian lighting, and other infrastructure improvements.

The largest urban brownfield redevelopment in the United States, Atlanta's Atlantic Station sits on 138 acres adjacent to midtown Atlanta on land once occupied by the Atlantic Steel Company, a steel mill that was active between the 1920s and 1980s. Authorized in 2001, the TIF designated funds for environmental remediation, general site work, utilities, and transportation infrastructure. In 2006, this TIF generated over \$8 million in revenue. Bike lanes were added to the streets, and wider streets will eventually accommodate a dedicated transit line. Currently, Atlantic Station

provides its own free trolley shuttle, which runs every five minutes.

A 2012 study revealed the average vehicle miles traveled is significantly less in the area than the regional average, with residents traveling, on average, 7.8 miles per day. Twenty-five percent of total trips within the community were in non-single-occupant vehicles; the number almost doubled for residents and employees.

New York has used TIFs since the 1950s, but has never used the program as widely as other states. That may change since New York expanded its TIF law in 2012, allowing school districts to opt into the program. Even before the change in statute, the extension of the No. 7 subway line of the New York Metropolitan Transit Authority (NYMTA)

was financed by the sale of \$2 billion worth of New York City municipal bonds. Using TIFs, New York City raised \$1.4 billion slated for the subway extension; the remainder of the funds will be used for other infrastructure improvements in the Hudson Yards area.

Taxi Drivers and Labor Issues

Taxis play an important role in urban and, to a lesser extent, rural transportation. Taxicabs are popular symbols of modern urbanity, and their drivers are at the forefront of public consciousness as an omnipresent participant in urban street culture. A mobile and divided workforce, taxicab drivers face a number of health and economic risks in the course of their daily work, while often remaining relatively powerless to affect the regulatory and employment structure of their work environment. Because taxis are non-fixed-route transportation, taxi drivers play an unusually central responsibility in the management of their own work time and the servicing of the public; thus, driver skill and the viability of taxi driving as an occupation are important, though sometimes neglected, concerns for policy makers seeking to improve the service quality of the industry.

A taxi (or taxicab or cab) is a general term applied to non-fixed-route vehicles for hire to the public, particularly in urban areas. The term is also sometimes used for semi-fixed route services, such as the bush taxis of rural Africa, or the shared taxis of South Africa. Local governments often apply the name more narrowly, in order to distinguish between several different types of such vehicle, depending, for instance, on the mode of hire (from the street or by prearrangement) and rate of fare, but, for the purposes of social science, it is simpler

to use the term *taxi* as a general designation for all such services.

The most common vehicles used as taxis are gasoline- or electric-powered automobiles, but similar services use motorcycles or bicycle rickshaws. Besides legally defined categories, there also exist varieties of informal taxis. These operate either by mimicking the signage and operation of formal taxis or as “vernacular” taxis, often unmarked, serving particular communities, such as ethnic or impoverished neighborhoods, which are underserved by the formalized taxi system. The labor issues described here apply most directly to formal automobile taxis, but similar conditions apply broadly to drivers of informal and nonautomotive forms.

Compared to other classes of transportation workers, such as public bus drivers, taxicab drivers typically have a lower income, less job security, and fewer employment benefits. This is at least in part the result of the taxi industry being the domain of private business rather than public transit, and because taxi drivers are often a disorganized and disunited workforce. Some of the causes and consequences of this are discussed below, beginning with the risks faced by drivers in the course of their work.

Occupational Hazards

Globally, and even within individual cities, the working conditions of taxicab drivers vary widely, because of differences in employment models and class context. Nevertheless, taxicab drivers everywhere face a similar list of occupational hazards, from the threat of injury or violence on the job to income uncertainty and the long-term health effects of spending hours in a vehicle in urban traffic.

Temporal variation in demand for taxis is a major problem faced by operators. Passenger demand can vary greatly according to daily, weekly, monthly, and seasonal cycles. The viability of taxi driving as an occupation depends on cross-subsidy, whereby income from busy times subsidizes slow times or when no business can be obtained. The timing of payments owed by drivers—vehicle leases, insurance, financing payments, inspection and licensing fees, and taxes—affects their vulnerability to income fluctuations.

Health risks associated with cab driving include wrist and back injuries resulting from repetitive motion, prolonged sitting, and lifting luggage; skin

cancer from exposure to sunlight; respiratory problems from breathing auto exhaust; possible physical harm from traffic accidents or assaults by passengers and/or robbers; and stress from prolonged attention to driving, dispatch, and the cab’s surroundings. The economic context of the occupation affects drivers’ exposures to these risks. Thus, the need to pay a cab lease, or to meet insurance or financing payments, may push drivers into working longer hours or taking more risks, such as speeding in traffic, or accepting potentially dangerous fares.

When numbers of drivers are high and competition for passengers is fierce (for instance, in cities with little or no restrictions on entry into the taxi business), drivers may turn to illegal means to supplement their income. Particularly in many developing world metropolises, taxi kidnappings and robberies of passengers are a sporadic threat. Nevertheless, taxicab drivers are generally more likely to suffer from violence than are passengers.

Although sometimes tolerated by police and regulators, drivers of informal taxis may also face the costs of fines or bribes to stay in operation, along with the risks of vehicle seizure or other penalties; for these reasons, informal drivers often operate at night or in marginal neighborhoods away from the sight of police, exposing them to further dangers of victimization.

Employment Context

Three interrelated factors play key roles in shaping the labor conditions faced by taxi drivers. These are (1) the relative amount of influence or control drivers have over their own working conditions, (2) the occupational prestige and class context of taxi driving as an occupation, and (3) the extent to which drivers are considered to be skilled or unskilled, and the extent to which driver skill is recognized or cultivated by regulation and the industry in general.

The amount of influence or control drivers exert over their own working conditions depends largely on the occupational structure and regulatory framework of the industry. In any given city, taxicabs may be organized into large fleets, or as a multitude of independent owner-operators, or as a mixture of both. For much of the 20th century, it was common for fleet drivers in parts of the developed world to be employees, often unionized, typically working for a commission or percentage of the income from taxi fares.

The later decades of that century, however, saw the resurgence of the 19th-century model of leasing or “horse-hiring,” with growth in the numbers of drivers renting vehicles by the day, week, or month. Lease drivers typically have fewer workplace protections than employee drivers, and, as in the United States, may be legally restricted in their ability to form unions (because they are considered to be independent contractors). This typically results in less access to health care, unemployment benefits, or workplace injury compensation. Whereas drivers working for a percentage will at least be sure of taking home some amount of income per shift, lease drivers may lose money if they do not make enough to pay for the rental of their vehicle plus gasoline and other maintenance expenses.

A third category of driver, the independent owner-operator, is common in many cities of both the developed and developing worlds. Classically, as the term implies, the owner-operator owns and operates his or her vehicle. However, more complicated possibilities exist. For example, an owner-operator may hire one or more additional drivers to keep the vehicle in operation for more hours, if this is allowed by law. Where permits are required to operate taxis, one individual may own both permit and car, and do the driving; or a driver may lease both permit and vehicle from one or separate owners, or any similar combination.

Individual owner-operators may work without any contact with other taxi drivers; in other cases, owner-operators may combine into driver associations. Driver associations provide many services: they may allow drivers to share dispatch resources (such as radio or computerized dispatch), they may petition for and maintain taxi stands for the use of the members, or they may provide vehicle and liability insurance. Driver associations also function as pressure groups for promoting the political interests of taxi drivers; for this reason, owner-operators often have a stronger political voice than lease drivers, particularly when the latter are not unionized.

Such differing employment structures may coexist in one city, leading to divisions between permit-holding, leasing, and owner-operating drivers. Such divisions among the taxi-driving workforce can be compounded by regulatory distinctions. Thus, when legal distinctions are made between modes of dispatch or hiring available to different classes of

vehicle, drivers are divided, as well, into competing and sometimes antagonistic groups.

New York City is an example of a city with such a divided taxi workforce: its taxis are divided among yellow cabs (allowed to pick up street hails downtown), black cars (which can only provide pre-arranged service), and livery cabs (which are legally limited to phone orders in certain parts of the city); the drivers of each of these are again divided among lease drivers and owner-operators. Such divisions make worker organization difficult and thus lessen the opportunities for drivers as a whole to influence the decisions of employers, regulators, or policy makers.

Social Status

The social status of taxicab driving as an occupation affects the way drivers are treated by passengers, employers, and regulators, as well as affecting drivers' own self-perceptions and their expectations about the working conditions and desirability of the job itself. Although taxi driving is a relatively low-status job in much of the developed world, this is not true everywhere. Taxicab driving is seen as a more desirable, higher-status job in conditions where it allows economic advancement or a path out of poverty, for instance, for rural-to-urban migrants.

In developing-world cities, access to an automobile in the form of a taxi may be a status symbol in itself, and taxi drivers may have higher incomes than many other sectors of the working class. Where drivers are able to purchase taxi vehicles and/or permits, upward mobility within the industry is possible, with career drivers turning into independent businesspersons over time, or even obtaining fleets of several taxis.

However, the lure of ownership may pull drivers into debt, a particular problem in migrant communities where members may be the targets of predatory lenders who specialize in loans to taxicab drivers. When permits or taxis are freely transferable, they may accrue in the hands of nondrivers, with prices outside the range affordable to working drivers. When the occupation does not offer possibilities of advancement, taxi driving comes to be seen as an occupation of last resort.

During economic downturns, it is not unusual for professionals and members of the middle class to turn to taxi driving for employment. Such drivers are less likely to consider driving desirable as a

career, and are less likely to seek improvements to their working conditions than to seek an exit from the occupation.

In much of the developed world, a large proportion of taxicab drivers are transnational migrants. In primary cities of the developing world, it is also not uncommon for many taxi drivers to be internal migrants from rural or impoverished regions of the country. In either case, linguistic and/or cultural differences may mark taxicab drivers as outsiders, sometimes exposing them to incomprehension or even outright hostility from the riding public. The self-perception of such drivers depends again, in large part, on whether they perceive the job to be a “stepping stone” to improved economic chances or a “dead-end” with little or no hope of advancement.

Skills

The above-mentioned economic and structural constraints notwithstanding, taxi drivers experience a relatively high degree of freedom in terms of mobility on the streets, and over their own choices of where and how to obtain business. In contrast to fixed-route transit, the service quality of the taxicab industry is dependent on the drivers' choices and desires to find and serve passengers, as well as on their skills in wayfinding, avoiding accidents or robbery, dealing with passengers, and anticipating demand. Such skills are the product of work experience or of training, but are not universally promoted by the organizational structure of the industry.

The classic exception is London, which requires prospective drivers of black cabs to complete an exhaustive course of study lasting up to three years. Training courses of shorter duration are increasingly common in other cities worldwide. Beyond such training, driver skill is necessarily the product of years of experience, giving regulators an incentive to cultivate career drivers. However, the economic structure of a given taxicab market, for reasons described above, may encourage high turnover of drivers rather than commitment to the job, resulting in high ratios of inexperienced, unskilled short-term drivers.

This lack of skill may be partially mitigated by the use of technology, such as GPS devices for wayfinding. The growth of computerized dispatch simplifies the assignation of drivers to fares, reducing

the need for drivers to anticipate and find demand. The recent spread of smartphone dispatching often combines both of these features, along with tools for constraining driver and passenger behavior, through control of payment and tipping, and of the exchange of information. Such technologies may partially make up for the lack of driver knowledge and skill based on experience but do not protect drivers from violence and injury as effectively as experience on the job.

Insofar as taxi service is dependent on driver skill, and so far as that skill is derived from experience, policy makers would find it desirable to promote the existence of drivers who approach the job as a career. This can be accomplished by assuring drivers of some voice in the decision-making process of the industry, as well as some protections against the exploitation of drivers by employers, lenders, or even other drivers.

One attempt at such protection is the limitation of the ownership of taxicab permits to active, licensed drivers, in order to prevent the control of the industry by nondrivers who profit from the industry but are not exposed to the occupational hazards involved. This reform does promote career driving; however, it does not necessarily protect drivers from predatory lending or from fluctuations in market value if permits can still be bought and sold among drivers.

Another protection is the formation of taxicab cooperatives, several models of which have emerged independently in different parts of the world. These are typically more formal than associations of owner-operators in that they bring large numbers of drivers and vehicles together into cooperatively managed fleets. Although some cooperatives have been regarded as successful, others have experienced degeneration, a process by which democratic management in worker-owned cooperatives degrades into less democratic forms. Once again, this is often associated with divisions in the workforce, particularly between permit-holding drivers and lease drivers. When cooperatives are formed among permit-holding drivers, they are likely to hire lease drivers who are not themselves members of the cooperative, thus resulting in an oligarchic rather than democratic workplace.

Taxicab Licensing and Regulation

Taxicabs are a ubiquitous travel mode in cities throughout the world. In nearly all cases, the taxicab market is regulated by cities to manage fares, limit entry to market, ensure geographic reach, promote public safety, and maintain other service characteristics. The taxi industry is one of the oldest types of public transit and has been subject to license requirements for centuries. The long history of regulation includes various periods of strengthening and weakening regulations, and taxicabs are an area of local transportation policy where there is substantial variation in regulatory approach across cities throughout the world.

History and Legality

London and Paris were the first cities to regulate the taxi market. In the early 1600s, the cities required licenses for horse-drawn hackneys and limited the total number of vehicles available for hire. Since then, limits on the number of allowed vehicles has been a regular feature of local regulations, and while the original intent to ensure that operators met minimum standards was worthy, limits to entry are problematic and lead to rent-seeking and monopolistic behaviors.

For-hire services are regulated at local levels in most cases. Cities, counties, and other regional

governments design and enforce the regulatory environment. In the United States, states either allow cities to regulate taxicabs as part of their police powers or, in some instances, states require that cities regulate the industry. There have been numerous court challenges questioning the legality of local taxi regulations, but the ability of cities to regulate the market has nearly always been upheld. The current era of smartphone applications—discussed in more detail in a later section—represents a new line of legal inquiry that may challenge the historical regulatory structure, but early court cases from technology companies against the taxi industry and regulators have had mixed success.

Local control over taxi markets means that they are structured differently across cities. There are a few dominant types of markets, however. In a few cities, such as New York, street hails are the only way to hire a yellow cab. In many other cities, street hails are illegal and taxicabs must be dispatched (or booked). Other cities feature taxi stands, and often airports have their own different systems for hiring cabs. There are also regulations about sharing taxis and where drivers are allowed to pick up passengers.

Street Hails

Street hails occur where taxi drivers cruise around in search of fares and potential passengers raise their arms—or hail—available cars. Most cities prohibit street hails because the method increases the potential for discrimination based on geography or appearance. Street hails also require price regulation to eliminate fare negotiation at the point of hire. The largest justification for not allowing street hails is that taxi drivers will only cruise in the neighborhoods, usually in the central business district (CBD), where they will be able to find an adequate number of fares. This means that much of the area that potentially could be served will not be. More critically from a policy standpoint is that the concentration of taxi activity in a wealthy commercial area general drains taxi services from areas outside the downtown. Hailing tends to create geographic imbalance between potential riders and taxis.

Street hails also raise the opportunity for drivers to discriminate based on what a passenger looks like. In New York City, the yellow cabs, which are limited to street hails by law, are required to take any fare for which they stop. Of course, the word

stop leaves open a great deal of interpretation. Stories of racial and ethnic discrimination are common where taxicabs simply won't stop for a hail, although the number of fares not picked up is hard to measure beyond anecdotes.

Also in New York taxi drivers will often refuse a fare based on geography and time of day. For instance, taxi drivers have a shift change in the late afternoon. Shortly before this change, it is difficult to hail a taxicab to get to certain destinations because of the drivers' concern about getting back to their base in time to turn over their car. While these discriminatory behaviors are the exception and not the rule, they are the kinds of objections used when most other cities justify their use of dispatched or prebooked taxicabs.

Prebooked

In contrast to hailing taxicabs, many cities require prebooking or dispatch models for service. Dispatch services require the rider to call a central number, or in some cases the taxi driver directly, and a taxi is sent to pick them up. Prebooked services also include cars that shuttle passengers to airports, limousines, and other commonly used services.

There are multiple justifications for prebooked services. Cities that wish to prevent discrimination based on location or appearance seek to limit cab driver discretion in choosing fares. Absent dispatched services, few taxiscabs would be found outside central business districts or airports (or, in some cases, train stations). Beyond discrimination, pre-booked services prevent cruising for passengers, which is inefficient travel and wasteful for all involved outside of a few dense areas. Dispatched services are operated either as a first-call, first-served system where taxi cabs are sent as needed or as a scheduled service.

Shared Vehicles

Most taxicabs are limited to transferring an individual or one set of passengers at a time. Although a group of friends may share a ride and end up at multiple destinations, multiple pickups are typically not allowed. There is a special group of taxi licenses that does allow for shared vehicles in some cities, and shared taxis are often encouraged in the wake of major disruption to conventional transit services. New York City has shared taxi stands in a few locations where passengers can share a ride

and fare between the business district and popular residential locations. In the aftermath of Hurricane Sandy in October 2012, which knocked out parts of New York's subway system for over a week, shared taxis and jitneys were indispensable for maintaining mobility within the city.

Many cities regulate how multiple passengers are treated as far as the fare. Some cities allow for a separate charge for each additional passenger, while others require a single fare for each trip. For passengers, being able to split the fare is a way to reduce the cost of taxi rides and may induce additional taxi trip making.

Regulatory Frameworks

License requirements that limit the total number of for-hire vehicles allowed are very common in cities throughout the world. Ostensibly, regulators seek to determine the optimal number of taxicabs to serve perceived and real demand, then set the limits accordingly. Yet, in practice, it is extremely difficult to know how many taxicabs are actually required for any given demand, and by maintaining an artificial ceiling in the number of vehicles allowed, actual demand is not revealed. Rather, rider demand with regard to the constraints of the number of available taxis and the costs of the fares are revealed.

The iconic New York City yellow cabs, for instance, are limited to about 13,500 medallions. The Haas Act of 1937 initially placed a cap on the number of allowed franchises in order to mitigate the negative effects of the "taxi wars." Too many cars searching for fares reduced the earning potential of drivers and the competition for passengers actually reduced service quality and made passengers and operators worse off. Under the medallion system, each licensed yellow cab is required to have a physical shield, about the size of a grapefruit, stamped on the hood of the vehicle. Medallions in New York City grant the right to the holder to cruise for hails anywhere in the city, as well as protection from price competition (fares are set by the Taxi and Limousine Commission of New York City).

The restriction on total medallions has two perverse results. First, the value of individual medallions reflects monopoly rents rather than efficient pricing. The other effect is that unlicensed cabs have an incentive to enter the market. In New York City, livery cabs first appeared in the 1960s and now

number more than 30,000. These cabs serve areas of the city where the yellow cabs do not ply the streets for fares. Since New York's yellow cabs primarily cruise only parts of Manhattan, most of the city's boroughs are served by alternatives such as liveries operating in a regulatory gray area.

Fares

Taxi fares are regulated to ensure adequate earnings to cover wages and operating costs, as well as to protect passengers from fraudulent behavior. Taxi services are an example of credence goods, which are economic goods with asymmetric information and potential for fraud. Auto mechanics and physicians are also common examples.

Credence goods rely on the seller to be credible because the buyer has little way of knowing the true value of the good or service being provided. While everybody knows that they should receive a second opinion when a doctor provides a diagnosis, soliciting competing bids for taxi travel is usually impractical for all parties.

Regulated fares eliminate the need for negotiation. This not only serves the customers well, it also speeds up the process of hiring a cab by avoiding haggling over the amount to be paid on each trip.

Public Safety

Public safety is the key consideration for regulators. Many transportation scholars and economists argue that taxicab regulations should be limited to those that ensure public safety, but, even with safety, there is substantial disagreement as to what is required. The bare minimum regulation requires that all taxicabs and drivers have adequate insurance and licenses.

Vehicle Requirements

New York City is famous for yellow cabs, and London is equally famous for black cars. These are iconic aspects of the cities by design. Cities recognize the value of distinctive colors and shapes of valuable taxi services. New York's yellow cabs have inspired cities across the globe to adopt similar shades of yellow to mark their official taxicabs. By signaling through vehicle standardization, passengers are assured of a safe trip for the stated fare.

Taxi regulations often require that taxicabs look a particular way. Colors, as mentioned, are one set of requirements. In 2013, after a series of legal

challenges from entrenched medallion interests, New York City created a special taxicab license that will serve the areas of the city not well served by the yellow cabs. These new outer-borough taxicabs will be painted a specific shade of apple green to set them apart from conventional yellows.

Checker Cabs were the standard for New York's taxi services for decades. Much like London's black cabs, the Checkers were specially designed and built for taxi services. Over the past few decades, competition from conventional auto makers has resulted in a mix of available cars as taxis, and many cities have introduced fuel-efficiency standards or hybrid-engine standards to encourage particular types of cars.

Vancouver, Canada, was the first city to introduce hybrid taxicabs in 2001. In 2005, San Francisco used a Clean Air Taxi Grant Program as an incentive to increase the number of hybrid taxis, and now about 50 percent of the fleet are hybrids. Chicago used a similar program that encouraged the use of hybrids and compressed-natural-gas vehicles, and the city reduced the initial mileage allowable for taxicabs new to service. As many taxicabs new to Chicago were old taxicabs from elsewhere, especially New York City, the Chicago taxi industry quickly upgraded the fleet to newer, more-fuel-efficient cars.

As mentioned, vehicle age is another aspect of taxis that can be regulated. In New York City, taxicabs must be replaced after three years. (This forced obsolescence also partially explains why other cities have many yellow taxis; they may be used New York City taxis.) While in service, most cities require regular inspections of the vehicles to ensure safety.

Less common than vehicle age, color, or propulsion are strict requirements for the specific make of a taxicab. Most cities have guidelines for what cars can be used, but places such as London and New York go further in requiring a particular model of car.

In 2012, New York City announced the Taxi of Tomorrow, a vehicle made by Nissan that will be the primary vehicle allowed for use as a yellow cab in the city. The Nissan model was chosen after a competitive bidding process, which had a few entrants. The city wants the Taxi of Tomorrow to be an iconic part of the streetscape, although adoption of the vehicle is subject to resolution of legal challenges because the car is not fully accessible under the Americans with Disabilities Act.

Economics of Taxi Markets

Labor concerns are prevalent in taxicab regulation. Unregulated taxi markets are subject to intense competition that drives down costs and profits. Unfortunately for taxi drivers, their wages are the only part of the cost of doing business that is not fixed. Cars, insurance, and gas are all exogenously priced and owners have little ability to reduce these costs. Taxi drivers are owner-operators, independent contractors, or hired employees, although most fall into one of the first two categories.

Regardless of whether drivers are owners or hired employees, their incomes can get squeezed to the point where taxi driving is no longer sustainable. While this is exactly how the market economy works, the challenge for cities is the process of reaching taxicab equilibrium. Passengers who depend on taxis and cities that rely on taxis

to complement their transit systems cannot afford to go through periods of over- and undersupply of taxis. This is one reason why cities attempt to limit the number of licenses.

Limited access to medallions has caused the price of medallions to skyrocket in many cities. In New York City, medallions now trade for over \$1 million. Even in markets such as Ottawa, Ontario (Canada), medallions fetch over \$300,000, and in Milwaukee, Wisconsin, where one man owns half of the allowed licenses, licenses trade for close to \$200,000.

In a competitive market, these prices signal that scarcity is a problem and that the number of medallions needs to increase. Yet, for taxi markets, these astronomical prices for the right to run a cab represent rent-seeking and monopolistic behaviors. Economic rents are those that are earned without adding value to the overall economy. For \$1 million

Official taxi licenses and the medallion system were introduced in 1937 and remain in place today. The medallion system limits the number of cabs on the streets and has been criticized as an entry barrier to the New York City taxi market. It is therefore believed to contribute to the black market for illegal taxicab operations, also known as gypsy cabs. On the other hand, many believe the medallion system helps better regulate taxis, thereby enabling the city to raise the standards of all taxis.

medallions, there is no benefit to the public or to drivers from these prices. The medallion owners, however, get rich for being lucky enough to own a medallion as the price increased.

Who is harmed by rent-seeking in taxi markets? Because fares are usually regulated, people fail to see that consumers lose out. The regulated fares are higher than they would otherwise be, but there are fewer taxicabs on the road than would otherwise be expected. Rent-seeking behavior by monopolists or oligopolists also reduces productivity gains and service innovations. In many cities where the number of available licenses fails to rise and fall with demand, informal taxi services pop up, as is the case with 30,000 liveries in New York. Ultimately, rent-seeking behaviors limit the potential of taxi services and increase the cost of the service to customers, while the lucky owners reap profits earned through regulatory capture rather than business acumen.

Technological Innovation and Regulation

Smartphones have become ubiquitous and feature many applications that assist travelers with information, directions, and schedules for transit services. Taxicabs are no exception.

Technology companies challenge conventional markets through innovative ways to hire taxis or nontaxi drivers. These companies, such as Uber, Lyft, Sidecar, and others, operate as either a digital dispatch service (also known as “e-hailing”) or as a facilitator of car sharing. A company like Uber does not directly own or operate the vehicles but, rather, allows riders to book a car and pay for it through a smartphone application. These companies argue that because they are not providing the taxi service, they are not subject to conventional licensing requirements. These arguments are currently working their way through the court system, but New York City, Washington, D.C., and San Francisco have already revised their rules about e-hails.

Unlike e-hail companies, applications like Sidecar connect riders with people who are willing to pick up passengers in their own cars. This approach is a high-tech version of “slugging.” Slug lanes usually form at tolled bottlenecks, such as bridges, and the way they work is that drivers will stop and pick up people waiting for a ride, who in turn share or pay the cost of the toll. Through this mechanism, drivers make better use of their excess capacity and lower their cost of travel.

Smartphone apps that match riders with drivers work by drivers signing in as available, and potential passengers indicating through their phone that they want a ride. If the drivers accept the call, they make the pickup and drop-off. Through these apps, people are able to pick up passengers for a few hours per week and cover much of the expense of owning their car. It is not surprising that the most interest in these services is in cities where the cost of auto ownership is extremely high.

Rideshare applications are not subject to conventional regulations, at this early stage. Both e-hail and rideshare promoters often call them “disruptive” technologies, and the applications may eventually force new regulatory structures. In North America, it is usually illegal for anyone except fully licensed taxis or limousines to require passengers to pay for a ride. However, it is not illegal for passengers to volunteer payment to help cover the cost of travel. To comply with the letter of the law, rideshare companies consider payment to the drivers a gratuity and not technically required.

Conclusion

Taxicabs and other for-hire car services are heavily regulated and have been for decades, if not centuries. Early justifications for regulation limiting the number of taxicabs available addressed real concerns about service quality and the viability of the overall market. With unlimited entries, there may not be enough potential riders to maintain socially optimal levels of service. Yet, limits on entry likely have the effect of undersupplying licenses relative to socially optimal levels.

Regulators must deal with economic concerns of rent-seeking and asymmetric information, as well as complicated issues surrounding labor. As private operators, taxi drivers typically earn less than unionized transit workers and have limited ability to raise fares. Yet, in many markets, taxicabs are a useful stepping-stone for immigrants and low-skilled workers. Regulators must balance the needs of the drivers and operators with the broader public.

Established taxicab interests must now deal with disruptive technologies and smartphone applications that threaten established interests and ways of doing business. While these new entries to market and service innovations challenge the operational status quo, they may possibly increase overall taxi ridership and services. The current technological

changes happening within the taxi industry are the most significant since the advent of the meter.

Taxicabs

Taxi services are part of public transit systems and should be considered in the context of passenger benefits and public costs. An examination of peer-reviewed journals in transportation, urban planning, and economics uncovers few studies that explore the personal benefits of taxi travel over the past few decades.

In the 1970s, a relatively large number of scholars were concerned with taxi service as a vital piece of the urban transportation system, but in the decades since, there have been fewer studies of taxi service. One exception has been economists looking at taxicab regulations, especially in the context of airport service. Most published articles are favorable toward liberalizing taxi policies, though there has been concern in the literature that poorly conceived deregulation may be ultimately harmful.

Taxi Services

Planning and policies for taxicabs are wide ranging. Though taxicabs are a minor mode by usage, taxi

services play an important complementary role to transit and other alternatives to auto ownership. The passenger simply wants to get between two known points, for instance, work and home after a late night in the office.

But the taxi drivers have different incentives and travel patterns as they spend many trips—but not necessarily miles—waiting or driving to pick up another passenger. Understanding these two travel markets for each taxi vehicle is challenging. A few studies modeled after demand for taxi service from passengers and others are more conceptual about the potential benefits of taxi services. Recently, many scholars have started to use Global Positioning System (GPS) data from taxis to model traffic flows and other aspects of the transport systems. Overall, however, taxicabs are a relatively unexplored aspect of urban transit, especially with regard to the accessibility benefits and the relationship to public transit.

With the advent of GPS in taxicabs around the world, there has been substantial new interest in taxis and traffic. Many GPS studies explicitly examine taxi driver behavior using the spatial data. This type of study is representative of current work, but by focusing on taxi driver behavior rather than rider characteristics and benefits, these studies leave a gap in the literature.

Even with the new interest in taxicabs resulting from GPS data, the role of taxis for personal travel is rarely explicitly studied. The travel behavior of taxi drivers tells only part of the travel story. Many open questions about driver behaviors are important for environmental and congestion mitigation.

Unlike conventional transit, taxicabs are not directly subsidized. Because there are no large public outlays to create and support taxi service, there is less reason for publicly funded research to model the cost-effectiveness of any investment. This reasoning helps explain why taxi regulations are studied, as regulations have an impact on public budgets and governance. Second, taxi service is viewed too often as a luxury good for the wealthy. However, data from the U.S. National Household Transportation Survey (NHTS) and the National Personal Transportation Survey (NPTS) show that the lowest-income households—the ones who are most dependent on transit—also take far more taxi trips than other income groups. Low-income travelers actually rely on taxis a much larger share of

their trips than the general population. One study from 1970 reported that households with incomes below \$5,000 (about \$30,000 in 2013) took about 30 percent of all taxi trips. These mode shares are consistent over time and are confirmed through recent NHTS data. The percentage of total trips made by taxi was between five and 10 times higher for households with zero or one car than for those with two or more.

An enduring challenge for the study of taxis is that as a complementary mode to transit, taxi usage is negatively affected by low levels of transit ridership. In most cases, travelers do not use taxis regularly unless they are going to the airport, but people in most cities do not take transit daily either. Taxis deserve greater attention because of the positive aspects of the service. Taxis have been found to have positive net benefits because of very low direct public spending.

The number of taxicabs allowed in any city is generally tightly regulated. Regulations that limit the allowable number of licensed taxicabs operating in a city help protect the viability of operations for drivers and license owners. Taxi licenses were originally capped in part to alleviate pressure on the existing road networks (or, as in New York City, to address market failure following the Great Depression), though there have been North American cities that have deregulated their taxi markets over the past few decades to mixed success.

In cities where the number of taxis increased after deregulation—a trend that has occurred in Seattle, San Diego, Phoenix, and other western U.S. cities—the increases were limited to hotel and airport markets. There has been little expansion of local taxi services, and the lack of expansion is potentially a lost opportunity to enhance transit ridership and decrease auto ownership by providing high-quality, door-to-door service. Certainly, an unregulated market for taxi licenses will have effects on taxi supply and quality, but these effects are ambiguous. What is known is that the numbers of taxi licenses have not expanded systematically with population growth or city size.

Researchers have reached broad agreement that there is a positive and meaningful association between the number of empty taxicabs and patronage. As the number of empty cabs increases, ridership increases. While this relationship is documented, the causal mechanisms are less understood.

There has not been a clear trend toward stronger or weaker regulations of taxi markets in cities worldwide, so the effect of increased taxicab supply on patronage is not well established.

Taxicabs are an important complementary transit mode that is relatively understudied in the literature. As a locally regulated transportation system that requires very little public outlay to develop, taxicabs represent an important opportunity to improve transportation choices for all people. As researchers work with the wealth of new digital data from taxis, patterns of usage and demand are being revealed that can help policy makers engage with taxicab planning and policy from a strong base of knowledge and a better understanding of the critical role taxicabs play in urban transportation.

Telecommuting and Telecommunications

Telecommuting impact on travel demand and the urban environment has been an important issue in transportation research for more than a decade. Transportation researchers and planners have been identifying telecommuting as one of the most important travel demand management (TDM) strategies for reducing road congestion and vehicle emissions, and thus saving energy and

improving air quality. This alternative solution will work well with other such strategies, such as car, van and bus pools, public transit, compressed work weeks, and flextime.

Telecommuting is continuing to very rapidly develop as a normal way of working in the United States and elsewhere. In the United States, the National Air Quality and Telecommuting Act established pilot telecommuting programs in five major U.S. metropolitan areas with the purpose of studying the feasibility of addressing air quality concerns through teleworking. Several U.S. states have established telecommuting programs for state employees and actively promote telecommuting in the private sector. Statistics from the European Union (EU) reflect that the proportion of employees involved in telecommuting in the 27 EU countries increased from about 5 percent in 2000 to 7 percent in 2005.

Defining Telecommuting

There is no common definition of telecommuting (or teleworking, as termed in Europe). The term *telecommuting* was coined in 1976 and defined as “the partial or total substitution of telecommunications, with or without the assistance of computers, for the daily work trip.” Most researchers have tried to establish their own definitions of the concepts. Some of the common definitions, on a more general level, are as follows:

- The combination of flexiplace, flextime, and electronic communication
- Working at home or at an alternate location and communicating with the usual place of work using electronic or other means, instead of physically traveling to a more distant work site
- Remote supervision in combination with reduced commuting
- Teleworking defined as working at home or a location closer to home than the regular workplace, using information and communication technology (ICT) to support productivity and communication

Telecommuting was originally conceived as a full-time and home-based option, and presumed to be suitable only for information-related workers. It is now recognized that telecommuting does not need to be full-time, and that jobs need not be

necessarily information-related to be telecommutable, though such jobs will remain primary targets for telecommuting.

Another form of telecommuting requires the worker to travel to a telecommuting center site, other than home, from which the employee works instead of traveling to a more distant central work location. This includes running a home-based business as one’s only job, moonlighting from home (for example, running a secondary home-based business in addition to holding another job), and/or working at nearby satellite work centers (local and neighborhood centers). An example of satellite centers could be those that Pacific Bell has established in Los Angeles and San Francisco.

Impacts of Telecommuting

Potential beneficial transportation impacts of telecommuting include reduction in highway traffic congestion, reduced emission of pollutants, and savings in energy and petroleum consumption. The actual amount and impact of telecommuting in any particular region, however, will depend on particular travel demand measures in place and other aspects such as local conditions and local transportation and land use environment.

A substantial number of efforts have been made to conceptualize the interactions between transportation systems and telecommunications applications. Researchers Patricia Mokhtarian and Ilan Salomon used the following four definitions to describe possible relationships between telecommunications and travel:

- Substitution assumes that some demand for travel will be replaced by telecommunications
- Modification, in contrast with the first, anticipates the introduction of telecommunications technology to increase the use of transportation systems; for example, trip characteristics are modified by using telecommunication technologies, by a shift in commute timing, location, linking, and trip chaining without affecting the total amount of travel
- Complementarity, which refers to the situation where both transportation and telecommunications systems will enhance the efficiency of each other

- Neutrality, where telecommunication has no foreseeable effect on trip making

Mokhtarian and Salomon classified impacts into three period classifications: short-term direct, short-term indirect, and long-term. They considered short-term direct impacts as the possible substitution or stimulation of travel due to telecommunications. Short-term indirect impacts would arise if time savings from the replacement of travel by telecommunications were used to generate other trips. Long-term impacts are associated with the changes of land use patterns facilitated by telecommunications. Theoretical studies examining the impacts on residential location and urban development indicate that telework may also contribute to increased urban decentralization and even generate more transport, but, so far, there is little empirical evidence of this.

On the effects of home-based telecommunication in order to substitute telecommunication for commute trips, some researchers observed a significant reduction in work-related travel and a contraction of activity space for telecommuters as a result of telecommuting. Those reductions are due to eliminating commute trips. They also found that telecommuters not only substantially reduced their trip making and the total distance traveled but also chose nonwork destinations that are close to home.

Similar findings by other authors displayed that the share of activities performed close to home increased considerably for telecommuters on telecommuting days, and there was a contraction in the size of the activity space for telecommuters on commuting days. Findings of some studies supported an idea that telecommuters live farther from their jobs than non-telecommuters, but the substitution effect of telecommuting prevails because the longer commute distance of telecommuters is offset by the lower frequency and high speed of these trips.

In terms of the quantity telecommuting impact on travel, studies generally found that this effect is rather small. Researchers argued that although telecommuters travel less than non-telecommuters, the overall effect of telecommuting is less than might be expected.

In assessing the potential impact on vehicle miles traveled (VMT) or total person miles traveled, one researcher found a 27 percent reduction in personal vehicle trips and a 77 percent reduction in vehicle

miles traveled (VMT) on telecommuting days compared with days before they telecommuted. This finding is consistent with findings of other studies.

Dennis Henderson and Mokhtarian found that telecommuters have 32 percent fewer trips and 67 percent fewer VMTs on telecommuting days than on non-telecommuting workdays. Salomon, Mokhtarian, and Susan Handy consistently found that the overall effects of telecommuting are no more than 1 percent of total household VMT.

Mokhtarian suggested that "overall substitution effect of telecommuting will remain relatively flat into the future, even if the amount of telecommuting increases considerably." More recently, Sangho Choo and others conducted a multivariate time series analysis to estimate the impact of telecommuting on total VMT for personal transportation, using aggregate nationwide data. Their conclusion is that telecommuting reduces annual VMT, but by a very small amount—less than 1 percent.

Henderson and Mokhtarian also found no significant differences between noncommuting travel on telecommuting and non-telecommuting days. This result is echoed by others.

Despite the extensive research on travel effects of telecommuting, studies do not have a good estimate of the amount of travel that will be substituted or generated when saved commute time is available to a telecommuter. Handy and Mokhtarian discussed the various ways that telecommuting is measured and difficulties involved in comparing estimates from different surveys. In other research, the data reported telecommuters differ across studies depending on whether a survey includes self-employed people, independent contractors, part-time workers, or workers with more than one job.

Determinants of Telecommuting

The advances in information and communication technologies over the past decade may have changed some of today's employees' preferences and attributes. However, the adoption of telecommuting, in general, is still taking place more slowly than its strongest proponents expected, perhaps because of the diversity of various attributes and constraints. The reasons and motives for telecommuting are related to organizational characteristics, type of job, relations between employees and management, relations among fellow employees, and characteristics of the household and the individual.

Commute distance is considered to be one of the primary factors that influence workers' propensity to telecommute. In most telecommuting studies, telecommuters had longer commute distances than other workers. Studies also reported that employees who have stressful commuting trips, including traffic congestion, are likely to telecommute more frequently than others.

A financial incentive also influences the decision to telecommute. If the worker is given a salary increase for telecommuting, he or she is more likely to telecommute, while if there is a financial cost for working from home, workers are less likely to telecommute. Time squeeze for employed parents, especially the mother, has been put forward as one reason for a person teleworking, as well. Several studies indicate that women opt for flexible work arrangements for better child care arrangements, whereas men use these arrangements for other job-related reasons. Mokhtarian and her colleagues found that women were more likely to mention family benefits as a motivation for teleworking than men were. Mokhtarian and Salomon also found that greater income and education facilitated telecommuting, whereas age tended to act as a constraint.

Overall, it can be concluded from considerable literature in this area that telecommuting is linked with diffusion of new information and communication applications and services, and is influenced by both work-related and sociodemographic factors of telecommuters.

Telematics

When used in reference to the automotive industry, the term *telematics* refers to the integration of telecommunication and information systems into vehicles, resulting in an improved driver or passenger experience and additional safety features. The benefits can be summed up as added "vehicle intelligence." The essence of telematics in vehicles is this intelligence, combined with increased options for connectivity and communication with other sources of information, media, and, potentially in the future, other vehicles.

Technological Convergence

There is a greater trend in the field of technology and innovation—that of "convergence." With increasing sophistication of microelectronics, the boundaries between distinct and separate electrical devices are being blurred. In the past, you would have a telephone for phone calls, a record or CD

player for music, a “wireless” for radio reception, and a television for moving pictures.

With digital electronics and file formats, there has been the emergence of devices that fulfill multiple needs. Mobile phones are able to play multiple types of media and act as entertainment devices; laptop computers are able to make phone calls using Voice Over IP (VoIP); and smart televisions are able to browse the Web. Computers, once used as machines of work, now fulfill entertainment functions.

Within information technology (IT), the types of devices used for work and communication are changing with the rise of mobile computing and the tablet. Within the vehicle, there is now the provision of entertainment, but also devices that allow work and communication while drivers and passengers are on the move.

With increasing complexity, these systems can now integrate with vehicle sensors and systems to provide communication between the vehicle and the wider world to provide enhancements to the driving experience.

Further, it is likely that the sophistication of in-car telematics is only going to increase and the degree to which vehicles can integrate with existing media and communication devices will follow a similar pattern. It is this increasing integration and the blurring of boundaries between devices that is the hallmark of technological convergence—and it is at this intersection of technologies that the potential for exciting developments in vehicle telematics is seen.

The Electrification of the Motor Vehicle

The ever-increasing integration of telematics technology into motor vehicles can be seen as part of a continuation of the trend toward increasing “electrification” of the vehicle. Since the very early days of the motor vehicle, the steady incursion of electrical technologies replacing mechanical devices has added ever greater degrees of sophistication and precision.

Early mechanical wipers were motorized; mechanical distributors have been replaced with electric ignition systems, and carburetors with electronic fuel injection. Even mechanical hydraulic power steering is being subsumed in favor of electrical alternatives in some vehicles. The development of hybrid vehicles—as a transition technology to future ultra-low-emission vehicles continues this trend.

Next-generation vehicle technologies based on electric power trains with battery and fuel cell energy storage will potentially eliminate many of the mechanical systems of the traditional motor vehicle in favor of electrical equivalents. With this trend toward increasing electrification, modern vehicles have a multitude of sensors collecting data about the vehicle condition, performing diagnostic functions, and sensing the vehicle’s environment.

Further, as ever more functions are actuated electrically, by motors and solenoids, modern telematics systems have the ability to acquire data from the vehicle and act upon it. Telematics integrates these vehicle systems with communication technologies that allow the vehicle to communicate with the outside world to collect and broadcast additional data. Through this interaction with other sources of data and devices, there is the potential to add significant value to many aspects of the driving experience.

In-Car Entertainment

In-car entertainment has grown in its complexity. From humble origins—radios, cassette and eight-track players—modern telematics offers a dazzling array of media options. In many countries, analogue FM/AM radio is being phased out to free up radio spectrum for new digital services.

These technologies (DAB, DRM in Europe, ISDB-T in Japan, and HD-Radio in the United States) and alternative satellite radio services all offer the possibility of conveying additional information not possible with analog radio. As mobile data become cheaper and more ubiquitous, with improving communications technology, streaming radio from the Web may also be an option in the future.

Modern telematics can use additional information that can be communicated with digital radio to improve the entertainment experience. In addition, the most sophisticated in-car players will not only accept modern disc formats such as Blu-ray, DVD, and CD for audio, visual, and navigation content, but also an increasing range of digital media options such as USB, SD-Card, and other proprietary alternatives. Many manufacturers offer the option to interface with digital media devices, as well. In its most basic implementation, this is just a “dumb” auxiliary audio input, but more sophisticated implementations access and control devices are using dedicated interfaces that connect either physically or wirelessly.

Telematics systems can provide useful, if not sometimes critical, information to the driver of a vehicle. These systems typically use the Global Positioning System (GPS) to locate the driver of the vehicle on a road in the system's map database.

In many countries, there is legislation that the driver cannot be distracted while driving by in-vehicle entertainment features. In some markets, this means that entertainment applications of telematics are constrained to rear-seat passengers. High-end telematics integrates screens into the rear of the front seat headrests; headphone sockets provide bespoke audio to those using the devices. Video entertainment can be delivered by disc or solid-state device. Increasingly, with vehicle connectivity, there is the ability to access the Internet and stream media.

In-Car Communication

Early attempts to offer in-vehicle communication were radio-based and cumbersome. With the ubiquity of mobile phones, dedicated in-car phones are becoming increasingly rare. Primitive integration of car phones focused on a “cradle” to make physical connection with the phone, but now with improvements in short-distance wireless communication, the in-car telematics communicates with the occupants' phones wirelessly.

Smartphones can often be accessed via Bluetooth wireless technology, and telematics systems allow calls to be made hands-free, with telematics

also providing enhanced features such as voice dialing and steering-wheel phone controls to make communication on the move safer, which is increasingly essential because the use of handheld mobile phones by drivers is being banned by many countries and U.S. states.

What makes telematics systems unique is that in addition to offering hands-free functionality, the communication experience can be integrated with vehicle entertainment systems. Communication devices may also be used to exchange data and information with these systems.

Smart functionality can be added, too. For example, after sensing a vehicle crash or accident, the vehicle can summon assistance. Diagnostic information from the vehicle can be readily exchanged with service agents to diagnose vehicle faults remotely. Systems such as OnStar integrate the in-vehicle systems with paid-subscription call centers, which provide premium services to the vehicle owner. This powerful integration of vehicle telematics with added service features provides added value to vehicle owners.

Driver Information Systems

Telematics systems can also be used to communicate additional or enhanced information to the driver of the vehicle through advanced sensing or communications technologies.

One area where telematics can provide useful additional functionality is in the provision of traffic information to drivers. Traffic information is collated by a range of sources and can be used in a passive way—providing the driver with basic information on congested routes—but there is the potential for it to be used in an active way, that is, interpreted by navigation systems dynamically to optimize the shortest route. Information can be gathered from a multitude of different sources and services.

Navigation and Tracking

One area where telematics systems have become almost ubiquitous is in the field of navigation systems and vehicle tracking. Navigation systems have long been available as aftermarket options. As the technology becomes cheaper, it is increasingly common to see them manufacturer-fitted. Integrating navigation systems with the vehicle creates many smart opportunities for the vehicle systems to interact intelligently with the navigation system.

In some modern integrated navigation systems, the system is able to communicate with vehicle systems, providing features such as signaling preemptively as the driver approaches a turn. By combining topographical data with navigation-route data, vehicle systems are able to make intelligent decisions, such as selecting a lower gear when going up a hill if the car has automatic transmission. Where a Global Positioning System (GPS) signal is unavailable, integrated telematics systems are able to use “dead reckoning” based on feedback from vehicle sensors to gauge the vehicle’s position.

Through supplementing on-board navigation data with external communications, future telematics systems will be able to update maps with dynamic information about new roads or map changes. Navigation systems traditionally provide points of interest functionality. Future telematics systems will provide the potential to source even richer information about points of interest from the Internet.

Reading the Road

In addition to receiving information externally about a vehicle’s environment, increasingly sophisticated software, combined with the falling price of advanced sensors, is allowing vehicle telematics to sense the environment directly. Using a courtesy mirror camera, it is possible for a vehicle telematics system to “see” the same view as the driver. Using machine vision technologies, telematics systems are increasingly able to interpret features of the road ahead.

They can be programmed to recognize road signage and use this information to reinforce driver awareness. For example, by recognizing the signed speed limit in the zone the car is driving through, the telematics system is able to provide feedback to drivers if they exceed the speed limit. This could also be augmented by information from safety cameras stored in the navigation system.

Further, these machine vision technologies, augmented with additional sensors, are able to “read” the road surface and look at the position of the vehicle in relation to the white lines. Small corrections can be made automatically or, if a large margin of error starts to occur, feedback can be provided to the driver.

Telematics systems can also contribute to improving vehicle safety. Sensing hazards ahead, a vehicle

telematics system could retransmit this information to nearby vehicles that are enabled to receive the information, while flashing hazard lights would warn drivers approaching from behind. One example of a telematics system that can improve vehicle safety through reading the road is “night vision.” A camera placed behind the grille of the vehicle records images at night and highlights potential hazards to the driver using a heads-up display projected onto the windshield.

In addition to monitoring what is going on outside the vehicle, there is also interest in monitoring what is going on inside the vehicle. Such systems can be used to monitor driver fatigue and ensure that the driver is alert and focused on the road ahead. Should a driver’s concentration start to dip or should signs of tiredness be detected, stimulus can be provided. This could be audible, a vibration in the seat, or an interface with the vehicle comfort systems that would be set to provide a bracing cool breeze to make the driver more alert.

Applications of Telematics

The development of technologies to track vehicles’ locations, combined with smart payment technologies and applications for smartphones, has allowed the development of smart and flexible car-sharing services and clubs that offer vehicles on a “pay as you drive” basis. The inclusion of this sophisticated technology has added additional flexibility (or, as some see it, competition) to the car-rental business model, making it more convenient to users and reducing the barriers to making a car rental transaction. The smart technology has reduced the need for users to pick up vehicles from large centralized hubs, while the smart payment technologies reduce much of the administrative overhead of car rental.

The vehicle telematics system communicates GPS information about the vehicle’s whereabouts over the Internet. Users can then use an app on their smartphone to identify a nearby vehicle that is available for rental. Using a smart card or an online validation service, the vehicle is unlocked, giving the user access. The vehicle then can be driven, and its whereabouts tracked by GPS.

Users could be asked to fill the tank when it is one-quarter full using a fuel card provided. Users are billed for their car rental either by time or by mileage. Car clubs are seen as a vital tool to reduce

vehicle ownership and to promote sustainable technologies. Telematics technologies are enabling new business models that make this possible.

Fleet Management

Some companies are heavily reliant on transportation as part of their business model. This entails managing a large number of different vehicles. The physical location of vehicles is important, as the vehicles are company assets. Furthermore, the cost of running the vehicles is in proportion to the amount of miles they travel. Using telematics to track vehicles protects assets and prevents the abuse of them for non-company-related business. Through providing statistical data on vehicle performance, telematics can help fleet managers identify and diagnose problems early.

Insurance Risk Management/Reduction

Assessing and managing risk is what insurance companies specialize in. However, given the limited amount of data that insurance companies have on a high-risk group such as new drivers, it is challenging for them to make effective decisions about how to charge such drivers for insurance services. High-risk groups, such as young drivers, often get saddled universally with high premiums, which take into account statistical averages and ignore individual behavior.

Telematics technologies enable the collecting of actual in-car data about driving behavior and allow companies to reward good driving with lower premiums. Drivers can choose to have a box fitted into their car that will contain a GPS system, data logger, possibly an accelerometer sensor, and some means of communicating with a base station.

This “black box” logs driving behavior and notes anything perceived as poor driver behavior, including excess sudden braking, high speeds around corners, breaking speed limits, and unnecessarily rapid acceleration. The device automatically reports this data back to insurers to allow premiums to be adjusted. There may also be agreed rules between the insurer and their clients on specific behaviors that are being enforced, such as nighttime curfews for beginning drivers. Through having these telematics technologies fitted to a vehicle, there is an incentive on the part of the drivers to ensure that their driving behavior is impeccable. Insurance company statistics seem to demonstrate that cars

fitted with such devices have fewer accidents than those without in-vehicle telematics.

For the future, there is also the potential to integrate driver feedback into such systems. For example, rather than just passively monitoring driver behavior, such systems could make more active interventions, giving hints or feedback via a driver information display.

The Future of Telematics

While present telematics systems focus on augmenting the information that is available to the driver and providing assistance and prompts, the ultimate goal of telematics would seem to be the creation of an “entirely safe” vehicle. Volvo is one manufacturer that has set a goal of making a vehicle that “cannot crash” within a decade. This will doubtless include a significant element of telematics technology.

Looking further down the line, vehicles that drive themselves are another evolution for telematics technology. General Motors (GM) has demonstrated a prototype concept vehicle—ENV, designed for urban environments—that would be able to drive itself through the use of advanced telematics. The vehicle could also communicate with other vehicles traveling in convoy, making a larger “virtual” vehicle out of several smaller units.

Telematics systems could enable radically different configurations of vehicle, as shown in the GM ENV concept. By linking smaller vehicles virtually into what would effectively be a larger vehicle, the convoy of self-driving vehicles would provide greater utility than cars driving individually, but with the commensurate energy savings of only needing to use the exact amount of energy to move the number of people being transported on a given trip.

Communication systems would allow occupants in adjacent vehicles to talk to each other as if they were in the same vehicle. Automatic vehicles that drive themselves could answer many of the challenges of increasing urban densities, allowing vehicles to travel with shorter stopping distances as the human element of error is removed. That said, this loss of human control raises many interesting social, ethical, and policy issues.

Social and Policy Issues

Telematics technology undoubtedly has the potential to contribute greatly to social and environmental transportation goals. The improvement in

in-car entertainment is undoubtedly attractive to consumers, navigation systems offer better logistics and more efficient route planning, and safety systems have the potential to reduce some of the social impacts associated with vehicle accidents.

This added functionality and information must be balanced against the potential for distracting the driver from the most important task—driving the vehicle and ensuring the occupants remain safe. In many locales, there is legislation in place to ensure that, for example, video media systems are disabled while on the move. To what degree will motor vehicles as a product change in the future? Advanced concepts show how telematics systems could enable radically different conceptions of auto mobility, changes that will become increasingly essential given the growing population and resource constraints. These must, however, be balanced with ethical debates. As drivers hand over increasing amounts of responsibility to automated systems, the overarching question “Who is in control of the vehicle?” is a salient one.

Terrorism, Transportation Systems as Targets of

Because transportation systems are vital to a nation’s economic wealth, as well as movement of mass numbers of people, they offer attractive targets to any terrorists willing to further their own ideology or political will. Preventative measures have been formulated over the past decades, but the total elimination of terrorist activity from any transportation system may never be possible.

Transportation systems have always been seen as “primary” targets since the early days of warfare. By cutting army supply lines by means of bombing or acts of sabotage, the net result is an army deprived of both equipment and food, becoming demoralized. Because of this, defeat becomes inevitable.

Recent wars are full of examples of invading forces targeting communications and transportation systems as primary targets before inflicting casualties on the defending forces. The 1970s saw the advent of terrorism—an unlawful use of force by organized groups for ideological or political reasons—and the transfer of these tactics from the battlefield to the cities of civilian populations.

Most major cities have public transport systems that are frequented by the public. These systems—bus, rail, and underground railways (tube or subway)—move large numbers of people around a city quickly or cheaply (sometimes both). To a wider extent, regional, national, and international airports carry out the same task.

Airplanes as High-Profile Targets

A number of prominent international airline hijacks in the 1970s brought terrorism into the public arena. Terrorist groups hijacked airplanes, taking passengers hostage and finding a country to land in that was sympathetic to its cause. On most occasions, the hijackers surrendered without any hostages being harmed, but some occasions resulted in the deaths of a number of terrorists and passengers. As terrorist bomb-making became more sophisticated, the need for hijacking became redundant. Instead, bombs carried in suitcases were used that could evade detection systems at airports. Perhaps the most destructive terrorist attack on a passenger plane was the Pan Am Flight 103 Lockerbie disaster over mainland Scotland in December 1988.

The attack on the World Trade Center attack in New York and the Pentagon in Washington, D. C., in September 2001 was a throw-back to the 1970s in terms of terrorism. The terrorists hijacked the planes in flight, but instead of directing the pilot to fly the plane to a destination, the hijackers themselves took over the controls and flew them into their intended targets (with one plane forced down short of its target to crash in Shanksville, Pennsylvania). Although security screening had improved vastly from the 1970s as far as detecting sophisticated bombs, it had become lax in preventing weapons such as blades or knives from being carried onboard.

Another result of the advancement in sophisticated bomb-making techniques was the ease in which the various forms of ground transportation became easy targets. Any form of mass transit relies on its speed and ease of access to transport people from one place to another with minimal hold-ups. With terrorists (both groups and individuals) becoming more extreme in their views and dispassionate in their targets, ground transportation has come to the foreground in the case for legitimate targets.

Ground Transportation

In their attacks on transport infrastructure, and public transportation in particular, in England between 1973 and 1976 and again between 1991 and 2000, the Irish Republican Army (IRA) targeted the rail network around the country and the London Underground (subway). There were 22 bomb threats and explosions on the national rail network and 16 on the subway. Other targets included buses (three), roads (four), bridges (two) and the English Channel Tunnel. There were also many bomb warnings that turned out to be hoaxes or were defused, all adding to disruption of the transport networks.

Perhaps the worst attack on public transport in England occurred on July 7, 2005, when a series of coordinated suicide attacks targeting civilians took place during the morning rush hour in London. Four Islamist home-grown terrorists detonated four bombs, three in quick succession aboard three London Underground trains and one on a double-decker bus, resulting in 52 civilians being killed (as well as the four bombers) and over 700 being injured. The explosives were homemade, organic, peroxide-based devices packed into rucksacks.

Paris, Madrid, Moscow, Tel Aviv, and dozens of other cities have also suffered similar attacks in

recent years. New York's commuter tunnels and bridges were also a target of a planned al Qaeda attack in 1993 and the New York subways were targeted in 1997. Japan suffered the first attack on public transportation using weapons of mass destruction in 1995 when a Japanese doomsday cult released sarin gas into the Tokyo subway system, killing 12 people and injuring over 5,000 people.

Modern terrorism seeks to cause indiscriminate violence on as large a scale as possible. The next avenue for terrorists may be the use of chemical or biological weapons as a means to cause mayhem, as public transport systems are extremely vulnerable to this kind of threat due to enclosed areas and large numbers of people. As well as harming people in the subway, germs or gases could spread to areas above ground due to movement of trains through tunnels and ventilation systems exiting at ground level. In contrast, air flight can offer more protection against such attacks.

In comparison to other forms of transport, airplanes make relatively few passenger transfers and stops. Most airports around the world are situated in controlled locations where access to airplanes from the terminal buildings is controlled by few entry points and strict security procedures involving passenger profiling, metal detectors, x-ray equipment, and armed guards. None of these can be easily transferred to buses and trains as delays to these services would be costly and detrimental to the purpose of mass transport.

Ground transportation systems are vulnerable targets to any would-be terrorist attack due to their many access points and lack of security procedures. Small amounts of explosive carried in rucksacks are completely undetectable and can cause extensive damage and fatalities when detonated in crowded train stations or public transport interchange locations. Even if no injuries to people occur, disruption to the public transit system in any city will have a serious impact financially, as well as a demoralizing effect on the public using the system.

Mass public transport in any city is crucial to the economic growth and development of both local and national economies. It also offers attractive targets to terrorists seeking publicity. As was shown in London in 2005, small amounts of explosives can cause maximum damage in confined spaces, not only to the traveling public and transportation operations, but also to a region's economy and the

public's expectation of government providing basic protection to its citizens.

The Search for Greater Safety

How can transportation systems be made more resilient to acts of terrorism without compromising the ease of access, frequency of travel, and travel time? The airline industry has gone to great lengths since the 1970s to increase security in its operations from the time one enters the terminal building at the place of origin until one leaves the terminal building at the destination. As mentioned already, it is relatively easy for the airline industry to achieve this but, as with all operations, human error means that mistakes will be made; nothing is foolproof.

Ground transportation systems are faced with a different set of criteria than the airline industry. No ground transport system can, or will ever be, terrorist proof. But there are a number of options that can be used to help prevent acts of terrorism on these systems. These have been developed over the last 30 to 40 years, mainly in England as a result of IRA attacks, but can be applied to any transport operation.

A program called Crime Prevention Through Environmental Design (CPTED), formulated in the United Kingdom, carefully analyzed every terrorist incident that occurred over this period. From this analysis, a number of preventive measures were developed and implemented that not only protected lives but also reduced disruption to the public transport network.

These measures included dedicated staff in each police department advising local businesses on design and construction issues resulting from information gathered on blast effects on various buildings; improved visibility at stations for camera surveillance; blast-resistant litter bins located within view of closed-circuit television; improvement in fencing and lighting (bombs were often located in poorly lit areas); closed-circuit television with increased police patrols and prompt police response; passenger communications systems in many locations; extra staff and patrols; training of staff in the event of a terrorist bomb-warning or event; and the involvement of the public in detecting unattended bags and parcels.

This type of response is only possible in long-term continuing terrorist campaigns but can be adopted

A relief worker stands amid debris from the fuselage of hijacked United Airlines Flight 175 on the roof of Five World Trade Center on October 25, 2001, during recovery efforts in New York City after the terrorist attacks of September 11, 2001.

as preventive measures in any large city that has public transport networks. These security measures had their desired effect, as IRA terrorist attacks moved to areas farther afield on the railway network and to switch boxes and rail lines rather than stations, culminating in fewer bombs and more bomb threats. As in any public transport system, some things will never be achievable. Passenger screening and examination of all briefcases and parcels will not be practically possible for public transit systems used by large numbers of people daily.

No matter how much time and energy spent by any government is consumed by the matter of safety for the traveling public, this must be balanced against the cost-effectiveness of such measures. To make a public transit system totally safe, a prohibitive amount of money would need to be spent, but this would inevitably lead to a slower and more inconvenient system, which would result in people abandoning its use.

It would appear that a new phase of terrorism with regard to transit systems is now beginning.

With the continuing advancement in personal communication by use of the Internet and mobile phones, small terrorist cells are able to keep in touch when carrying out any terrorist attack. With terrorist attacks being perpetrated by smaller terrorist cells with no obvious affiliation to any organization, no public transit system will ever be safe.

The airline industry can continually improve on its security due to passengers having time to spend at terminal buildings waiting for connections, although smaller regional airports may not offer the same security levels. Regional or local flights can be used as an access point to any terrorist activity. Ground transportation, on the other hand, can only offer an after-the-event appraisal. Images of terrorists can only be established after the act, or attempted act, of terrorism has taken place.

There is no doubt that surveillance measures discussed above will help the public feel more secure, while offering the security services a method of identifying suspects. However, there is also another way that may help prevent any large-scale fatalities in the number of passengers using a public transit system, but this would involve a move away from the current practices prevalent in older cities around the world.

Where a city has three different types of public transit systems operating (bus/subway; bus/rail; subway/rail), these systems usually operate as separate entities. As already mentioned, this results in confined spaces where explosive devices can cause maximum damage to both the traveling public and surrounding structures. The solution is in the form of a multimodal interchange where the different public transit systems can come together and provide a seamless interchange for passengers between the different forms. Examples of this kind of interchange already exist in a number of European and American cities where space, light, and facilities—in the way of retail outlets—as well as a number of safety measures including closed-circuit television and open spaces, offer the traveling public a safe environment within which to travel.

London has also shown, through both private and publicly funded redevelopment, how existing transit systems in old, established city centers can be designed and implemented. Broadgate, a privately funded redevelopment of Liverpool Street and its surrounding area, provided a modern intermodal transport link between the subway, national rail,

and buses. King's Cross/St. Pancras—once the site of a horrific fire back in 1987 when 31 people were killed—is now a multimodal interchange where subway (tube), national rail, international rail, bus services, taxis, and bicycle parking facilities deal with over 95 million passengers a year.

The Stratford Interchange in London, built as a primary hub for access to the 2012 London Olympic Games, is an example of where a new transport hub facilitated local regeneration. This interchange acts as a terminus for the Jubilee Line Extension (subway), Docklands Light Railway, and the Local Over-ground Railway, as well as an interchange with the National Railway, the Central line (subway), and local bus and airport coaches. It also has a new civic square, a high-quality bus station, cycle parking with good natural surveillance, and convenient drop-off and pickup points.

Transport systems will always be a target for any terrorists willing to further their own aims. With the provision of counterterrorist measures, together with open, expansive, and modern intermodal changes, the effects of any terrorist attack can be reduced and the public treated to modern, efficient, and inviting ways to travel on public transit systems.

3-C Planning Process

Transportation planning in the United States, which initially was highly localized, has evolved to become more regional in outlook today. A causal change agent of this evolution was passage of the Interstate Highway Act of 1956. Establishment of the interstate highway system linked communities and even states that previously had only minimal connection with each other. Cities, states, and the federal government all were careful to guard their own interests, while at the same time gaining an understanding of the need to work collaboratively on transportation-related issues.

To avoid the parochialism prevalent in many communities and to tap into the expertise found in these same jurisdictions, the 1956 highway act was followed by the Federal-Aid Highway Act of 1962. With this act came a federal mandate for urban transportation planning in the United States. Specifically, the act required that all 204 cities of the United States with populations greater than 50,000 develop and maintain a transportation plan. Passed during the time when urban areas were planning their interstate highway routes, the 1962 act resulted in a significant growth of urban transportation planning. The 90 percent federal funding for interstate highway projects was another motivating factor for locales to develop transportation programs and policies.

The 1962 act is also considered to be a landmark piece of legislation in that it required that planning in urban areas be "continuous, comprehensive, and cooperative" (3Cs) in order to qualify for federal funding. Cooperative was defined not only to include cooperation between the various scales of government (federal, state, local) but also between differing agencies at the same level of government. Continuous was defined as the necessity for periodically evaluating and updating the transportation plan. Comprehensive was defined to include 10 elements required under the 3C planning process.

All inventories and analyses required as part of the transportation plan included analysis of the following: (1) economic factors affecting development; (2) population; (3) land use; (4) transportation facilities, including those for mass transportation; (5) travel patterns; (6) terminal and transfer facilities; (7) traffic-control features; (8) zoning ordinances, subdivision regulations, building codes,

and the like; (9) financial resources; and (10) social and community-value factors, such as preservation of open space, parks, and recreational facilities, as well as preservation of historical sites and buildings, and environmental amenities and aesthetics.

Such a comprehensive list helped engender the mandatory cooperation between various agencies and levels of government. This approach to planning was required of urban areas that wished to receive federal funding. As urban areas were defined as regions, this act also helped spur the development of regional modeling.

Ultimately, the entities that became associated with this regional modeling and transportation planning were metropolitan planning organizations (MPOs). Comprised of transportation planners and representatives from local government, the MPO's mandate was to develop a four-year transportation improvement program, which was among the most critical functions of the MPO. The Bureau of Public Roads, which later became the Federal Highway Administration, worked with external collaborators to develop standardized planning methodology and transportation modeling.

Transportation planning involves evaluating, assessing, and designing transport facilities, generally highways, streets, and public transportation lines. The "L" trains in Chicago, shown here, are planned and developed by the Chicago Transit Authority.

The outcome of this work was the Urban Transportation Modeling System (UTMS), which was a four-step approach to transportation modeling. The variables in the model were trip generation; trip distribution; mode choice; and route assignment. Trip generation refers to the number of trips made per weekday per household and is dependent on household characteristics such as income and size. Trip distribution estimates the generation of trips and seeks to define such trips as home-to-work or home-to-nonwork destination, among others. For mode choice, a travel mode is selected as determined by household income, travel modes available, and travel mode costs. In route assignment, trips are assigned to the network. Ultimately, vehicle speeds are reduced and trips are assigned alternate routes.

to absorb shock, and a tread to provide traction. The use of compressed air as a cushion is what separates the modern (pneumatic) tire from older tires, which simply shielded wheels from damage. Nonpneumatic tires are still used for the wheels of things like lawnmowers and carts. The tire industry is one of the most important consumers of rubber, producing over 1 billion tires annually for over \$100 billion.

The National Highway Traffic Safety Administration (NHTSA) in the Department of Transportation, maintains publicly accessible databases of tire recalls and consumer complaints. NHTSA also maintains a database of ratings for 2,400 lines of tires for passenger cars, minivans, sport utility vehicles (SUVs), and light pickup trucks. The ratings reference the Uniform Tire Quality Grading System (UTQGS), which grades every tire on treadwear, traction, and temperature. Tire manufacturers are required to display the grades of their tires on the sidewall.

Treadwear compares a tire's wear rate to a control tire, which is assigned a grade of 100. The treadwear grade represents how long the tire lasted compared to the control tire. More than half of tires are graded 201–400, meaning they took two to four times as long to wear out as the control tire. Only 15 percent are graded below 200, and about a quarter are graded between 401 and 600. Safety concerns make it important that tires be replaced when the tread is less than 1/16th of an inch. The "penny test" is an old one that still works: Insert a penny into the tread (Lincoln's head first). If the tread does not cover any part of Lincoln's head, the tread is worn too low. Modern tires also have tread wear indicators that mark when the tire needs to be replaced. Tires should be rotated regularly to prevent uneven wear.

The traction grade rates the tire's ability to stop on wet pavement and is graded C, B, A, or AA (essentially an A+). Only one line of C-rated tires is sold in the United States. Seventy-five percent of tires are rated A for traction, with a small number (3 percent) of high-performance AA tires and a somewhat larger number (22 percent) of B-rated budget tires.

Temperature grades rate the tire's resistance to heat. Blacktop becomes especially hot in the summer, and in combination with sustained driving, this can lead to tire deterioration, tread separation, or blowouts. Temperature is graded with a simple A, B, or C. Most tires are graded A.

Tire Safety

Modern tires are ring-shaped covers for vehicle wheels and provide both traction with the road surface and a cushion to help absorb shock. Made of both natural and synthetic rubber, each tire has both a body, which contains compressed air

In addition to the UTQGS ratings, federal regulations require other information to be displayed on every tire, including the vehicle type for which the tire is intended (P stands for passenger vehicle), a three-digit number giving the width in millimeters from sidewall edge to sidewall edge, a two-digit number giving the ratio of height to width (with lower numbers, and thus shorter sidewalls, resulting in better handling on dry roads), an R for radial construction (the industry standard, though there were once other options), the diameter of the rim in inches, the load index indicating how much weight the tire can support, an M/S or M+S to indicate the tire has some mud and snow capability (which is true of nearly all radial tires), a letter rating indicating its speed rating, the Transportation Department tire identification number used for recalls or customer complaints, the tire ply composition and materials used, the maximum load rating, and the maximum permissible inflation pressure as mentioned above. The letter rating used for the speed rating indicates the maximum speed capability of the tire. In addition to these items, tires for light trucks (marked LT) list the maximum dual and single load and tire pressure and the tire's inflation limits and load-carrying capabilities.

Preventing tire failure, to minimize the possibility of accident, requires that tires be properly maintained. Basic tire maintenance consists of checking the tire valves and making sure they are capped and, on long trips or transporting unusually heavy loads, checking tire pressure at regular intervals. Additional safeguards include not overloading the vehicle, not pulling a trailer that is too heavy, and inspecting tires regularly for signs of wear or trauma, looking for cracks, embedded objects, uneven wear patterns, or loss of tread depth.

The tire information placard attached inside the vehicle by the car manufacturer—usually inside the trunk lid, on the glove box door, or on the vehicle door edge—specifies the vehicle capacity weight and often the gross axle weight ratings (which are always included in the user's manual). These indicate the maximum weight that can be carried by the vehicle and by the axles, respectively. Rubbing over curbs, striking curbs from the side, and running over potholes and objects in the road contribute significantly to tire wear as well.

To properly function, tires must be inflated to the correct pressure, which varies by tire and

vehicle. Maintaining proper tire pressure is necessary to avoid blowouts and flat tires; it also improves handling and fuel efficiency. Because most tires are sold with the intent of being used on more than one make and manufacture of vehicle, the tire's maximum inflation pressure is listed on the tire sidewall.

Prescribed pressure applies to a cold tire, one that has not been used in the last few hours. Correct tire pressure for each car model (which is measured in pounds per square inch and is easily measured with a gauge that attaches to the valve) is noted not only in the owner's manual but in the tire information placard. Too much pressure makes the tire more likely to blow out as a result of a heavy load or contact with a sharp edge or foreign object. Too little pressure impairs handling, exacerbates the effects of a slow leak, and increases the wear and tear on the (considerably more expensive) rims the tires are protecting.

Tires must also be properly balanced and aligned in order to keep the car from shaking while driving as a result of weight imbalances. Those imbalances can also cause a car to list to the left or right while driving. Wheel alignments, usually performed by a mechanic and requiring special equipment, adjust the positions of counterweights on the wheel that balance the weight of the wheel and tire assembly.

In snowy northern areas such as the Northeast and the Upper Midwest, many people use snow chains or snow tires for improved traction in the winter. Snow tires differ from regular tires in a number of ways. Their rubber composition is usually softer compared to other (all-season or all-weather) tires, providing better grip at cold temperatures. The tread is deeper, often significantly so.

In some places—the entire province of Quebec, for instance—use of snow tires is mandatory for the coldest months of the year. In other places, the use of snow chains is preferred. Snow chains are placed over the tires and so can more easily be taken on and off as the weather dictates. They increase the traction of the tire while reducing the speed (sometimes significantly) and fuel efficiency. Because snow chains do much more damage to the roads, their use is illegal in some areas.

Legal conditions vary significantly: Alaska permits their use whenever safety requires them in order to avoid skidding and sliding, but bans them during the warm months (April or May through

September, depending on the latitude); Colorado, on the other hand, requires them on certain posted roadways, and New York requires them during any declared snow emergency.

Toll Roads, Private

Over the past 20 years, the private sector has reemerged as an important player in transport, not only in the provision of highway design and construction, but, increasingly, as a project initiator and a provider of facility financing, management, operations, and maintenance. The extent to which traditionally public transportation facilities are partially or entirely privatized is based on a confluence of fiscal, infrastructural, and political factors, but, given current trends, it will likely result in an even greater role for private transportation infrastructure consortia in the future—accompanied by an increasing debate over its appropriateness and propriety.

And, as facility tolling has increased in popularity as a strategy to fast-track project procurement and leverage sources of private investment that might not be otherwise available, the private sector has recognized the investment potential of these projects.

Background

Historically, the private sector has played a pronounced role in providing highway transportation infrastructure in the United States. As early as the late 18th century, private companies were building and improving roads for foot traffic, horses, and carriages, and were recouping their costs by charging users a toll. The first American toll road for motorized vehicles—the Long Island Motor Parkway, completed in 1911—was privately constructed, operated, and maintained. Public toll authorities only emerged as part of the "good government" movement early in the 20th century, largely in reaction to malfeasance and mismanagement in the private contracting and financing of the Brooklyn Bridge in New York City.

Beginning in the 1950s with the construction of the interstate highway system, direct federal, state, and local funding of interstate and state highway facilities—through the General Highway Fund, direct congressional allocations, or publicly issued debt—dominated highway financing. This persisted through the 1970s. However, a confluence of trends over the next quarter-century encouraged the increasing involvement of private entities in various phases of surface transportation facility procurement.

During the President Ronald Reagan administrations in the 1980s, there was a devolution to the states of many traditionally federal infrastructural responsibilities, laying the foundation for the cautious encouragement of public–private partnerships in the procurement of highway facilities in the Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA), the 1997 Transportation Equity Act for the Twenty-First Century (TEA-21), and the 2005 Safe, Accountable, Flexible, Efficient Transportation Efficiency Act: A Legacy for Users (SAFETEA-LU). Each successive act provided funding for states to explore increasingly privatized models of new highway provision and expanded highway capacity.

In addition, the Transportation Infrastructure Finance Innovation Act of 1998 and the 2012 and 2013 Transportation Investment Generating Economic Recovery (TIGER) discretionary grant programs expanded the range of federal funding options for surface transportation infrastructure projects of national significance. Highway transportation facilities—especially those designed to

be toll facilities—developed or expanded over the past 20 years have been increasingly public–private partnerships of an increasingly diverse variety.

At the same time that the federal government was pulling back from its historically dominant role in surface transportation facility funding, a series of recessions in the early 1990s, early 2000s, and 2008 and 2009, combined with a persistent aversion by states and the federal government to allocate non-fuel-related tax revenues (through the General Highway Fund) to the increasingly necessary maintenance of the country's highway infrastructure, presented private entities a number of opportunities to form partnerships with state, regional, and local transportation agencies to provide those services and, often, the supporting financing.

Compounding this political and fiscal retrenchment is the increasing congestion, age, and frailty characteristic of a significant portion of the U.S. highway transportation infrastructure. Not only has much of the U.S. highway system passed its design lifetime, but there has also been an accelerating shift of the country's population to its urban centers, putting enormous stress on urban highway systems and resulting in high levels of congestion and attendant air pollution. Increasingly, federal, state, regional, and local transportation agencies are looking to the private sector to accelerate the development of facilities to accommodate this increased capacity demand.

From Public to Private Toll Roads

The traditional public toll road is one that is conceived, financed, operated, and owned (if not maintained) by a public transportation agency. It generates a usage-based toll revenue stream that is managed by the sponsoring agency with rates set as the result of a transparent, public, political process. While maintenance and/or operation of these toll roads may be contracted to private concerns, these facilities remain under public control because decisions related to the creation of the facility, its financing, and the management of the resulting revenue stream remain under public control. A private partner may be reimbursed for operations and maintenance services by performance-based “availability payments” from the public partner, which would be derived either from toll revenues or from general fund allocations.

The degree to which a toll highway is considered “private” depends on the nature of the partnership

between the public sponsor and the private entity and, ultimately, whether the public sector controls the toll revenue stream, facility operations, and rate setting. A purely private toll road is a new or expanded facility that is conceived, financed, constructed, operated, and maintained by a private entity or consortium in response to market demand as a profit-making venture for the entity and its investors.

One example of the for-profit model is the 22-mile Camino Colombia Toll Road near Laredo, Texas, which was developed by Camino Colombia, Inc., to give truck traffic swelling as a result of the North American Free Trade Agreement (NAFTA) a direct connection between Interstate 35 and the Colombia Solidarity Bridge (Bridge 3) over the Rio Grande to Mexico. The \$90 million project was completed in 2000 but declared bankruptcy in 2003 due to lower-than-forecasted traffic volumes. It is now owned and operated as a free highway by the state of Texas. A more successful example of a purely private toll road is the Dulles Greenway, a 14-mile privately conceived, constructed, operated, and maintained extension to the publicly owned Dulles Toll Road in Loudon County, Virginia.

Purely private toll road projects are rare because of the size of the investment and the risk that toll revenues will be insufficient to cover project expenses and generate an acceptable return on investment. Most private toll roads are public facilities for which long-term operations and maintenance (O&M) leases—or concessions—are granted to a private entity in return for a single up-front payment and access to the revenue stream generated by tolling the facility. Technically, the public owns the toll road, but responsibility and uncertainty associated with managing the toll revenue stream are transferred to the private concessionaire. The public agency benefits from the option to allocate the up-front payment to other priorities, and the private entity benefits by gaining a long-term revenue stream with which to repay project equity and debt investments.

Controversy

The arguments made in favor of private toll roads derive primarily from those associated with the putative superiority of an unfettered free market economy to respond to transportation facility demand more efficiently than public-sector agencies. Proponents of private toll facilities argue that a

free market is best situated to respond to state needs for providing additional or renovated capacity and facility operations, management, and maintenance. While federal and state transportation budgets are subject to ebbs and flows of political and fiscal will, the private sector responds to the desire of capital to find the best return on its investment, in theory. In this view, toll rates for these facilities are set best not by state regulators but in response to competitive market signals sent by user demand for the transportation capacity supplied by the facility.

In spite of the long-term risks characteristic of such projects, highway infrastructure development and management often meet those profit goals. Private transportation consortia often can leverage not only sources of capital unavailable to public-sector sponsors (for example, private equity stakes and market capital), but also may be able to develop or apply innovative management, construction, and operations technologies (for example, automatic tolling) to which public sponsors may not have access.

The quasi-permanent O&M concession granted by a public transportation agency to a private concern—often for as long as 99 years—is necessary, it is argued, to provide the concessionaire with time not only to recoup its equity investments and repay debtors for the original facility construction but also to compensate it for managing facility operations, maintenance, and new construction over the term of the concession. The term of the agreement is also necessary to mitigate the long-term risk associated with the uncertainty of facility usage and its toll revenue stream.

Many critics of private toll roads argue that tolling, in and of itself, has undesirable equity and fairness consequences, such as imposing additional transportation costs on those least able to afford it. (However, while costs for the individual driver may, indeed, be higher for a toll-financed highway, a recent study by Schweitzer and Taylor indicated that the low-income resident population pays more out-of-pocket for a similar facility financed by more egalitarian, sales-tax-based means.) They also point out that non-compete clauses often included in concession agreements unfairly favor the private facility by restricting expansion and/or improvement of public highway capacity in the vicinity of the toll facility.

However, issues of the public interest and of public versus private decision making generate the most controversy over the development and management

of private toll facilities. The granting by a public-sector transportation agency of an O&M concession to a private entity effectively removes from public debate and accountability issues such as the level at which facility tolls are set, the uses to which that revenue stream are put, and the quality of O&M services. More broadly, private ownership of transportation infrastructure interferes with broader transportation policy making and planning.

Many of these concessions have lifetimes that span several generations, and critics argue that awarding such contracts does not adequately address the best interests of future generations of facility users. Furthermore, studies have been conducted that suggest that the retirement of private debt, to which the toll revenue stream is directed during the concession, may occur in far less time than the term of the contract, leaving the private entity reaping far greater profits than it is due.

A controversial example of this sort of agreement is the 99-year O&M concession for the publicly owned Chicago Skyway, an aging and financially troubled 7.8-mile toll facility, which was granted in 2004 to a private operating consortium for \$1.83 billion.

Tourism

Tourism is a major contributor to economic development in many regions of the world. The term *tourism* is used to describe the following:

- Tourists, the individuals who engage in voluntary return mobility
- The tourism industry, those firms, organizations, and individuals that enable tourists to travel
- The broader social and economic phenomenon of tourism, including tourists, the tourism industry, the people and places that comprise tourism destinations, and the impacts of tourism on generating areas, transit zones, and destinations

Although widely perceived by the layperson in terms of leisure or vacation travel, tourism is defined technically in terms of the voluntary, temporary mobility of people for nonemployment purposes. This article outlines the economic significance of tourism, employment contribution, and implications of partial industrialization and impacts.

In distinguishing tourism from other types of population movement, several factors are important. Tourism is voluntary, return travel and includes neither the forced movement of people for political or environmental reasons nor permanent migration away from what was their home environment, although the distinction between tourism and migration is sometimes blurred because of extended return travel away from a home environment in another country. The statistical definition of tourism therefore depends on determining

factors of time (how long people are away from their permanent place of residence, usually less than a year) and distance (how far people have traveled or whether they have crossed jurisdictional borders). These considerations are vital in any assessment of the economic impact of tourism.

Global Economic Significance

According to the United Nations World Tourism Organization (UNWTO) in 2012, international tourist arrivals reached over 1 billion for the first time, up from 25 million in 1950, 277 million in 1980, and 528 million in 1995. Given that an international trip can generate arrivals in more than one destination country, the number of trips is lower than the number of arrivals. Although international inbound tourism is usually the primary national policy focus because of its role in international trade and business, at a global scale over 80 percent of tourism is domestic.

The role of domestic tourism in regional economic development policy therefore means that it is usually the focus of state, provincial, or regional governments. National governments tend to focus on attracting international tourist arrivals and, in some cases, seek to limit outbound tourism growth because of the economic loss it represents to a country's economy. However, some national governments do support domestic tourism initiatives as part of regional development strategies.

Even though the relative proportion of tourism's contribution to international trade in services has declined since the 1980s, tourism remains an extremely significant contributor to the global economy. According to the UNWTO, tourism ranks as the fourth-largest economic sector in the world after fuels, chemicals, and food, and contributes an estimated 5 percent of global gross domestic product (GDP), and 6 to 7 percent of employment (direct and indirect).

International tourism's export value, including international passenger transport, was estimated at \$1.2 trillion in 2011, accounting for 30 percent of the world's commercial service exports or 6 percent of total exports. Tourism is one of five top export earners in over 150 countries, while in 60 countries it is the number one export sector. It is also the main source of foreign exchange for one-third of developing countries and one-half of least developed countries (LDCs).

International tourism numbers have continued to increase since World War II and have only shown short-term decline or leveling off in growth at times of economic crisis, often related to energy and/or political crises. The UNWTO predicts the number of international tourist arrivals will increase by an average 3.3 percent per year between 2010 and 2030 (an average increase of 43 million arrivals a year), reaching an estimated 1.8 billion arrivals by 2030.

Most growth is forecast to come from the emerging economies and the Asia-Pacific, and by 2030 it is estimated that 57 percent of international arrivals will be in what are currently classified as emerging economies. At the same time, domestic tourism, especially in the emerging economies, is also expected to grow.

Contribution to Economic Development

Tourism has become increasingly important as an economic development mechanism since the 1970s as a result of globalization and restructuring, which has affected urban and rural economies in the developed world. For example, the European Union's European Regional Development Fund, which was established in 1975, utilizes tourism as a development strategy because it is perceived as being highly labor intensive and a counterbalance, along with other service industries, to job loss in the agricultural and manufacturing sectors. Tourism is also important to the economies of many small island states and LDCs, where there are limited economic development options.

There are a number of reasons why tourism is perceived by policy makers as a potential economic development mechanism. Of great significance are the diversity of the businesses that make up the destination product and the travel component provides for circulation of tourist expenditure through a number of different sectors. The supply chain to tourism businesses can also provide significant employment and economic opportunities, particularly in areas such as the provision of food for tourists, which flows through to the agricultural and horticultural sectors. In the developing country context, tourism may therefore also create business opportunities in the informal economy, as the barriers to entry and start-up costs are relatively low.

Tourism is also regarded as a labor-intensive industry. This has become an important issue where economic restructuring has led to unemployment

in traditional industries and where there are few employment alternatives. In the less developed countries, institutions such as the World Bank and the UNWTO have argued, tourism is important in tackling poverty given the sometime lack of development opportunities. Of particular importance is the relatively low skill requirement of some tourism employment, such as hotel room cleaning and restaurant service, which therefore also implies low training costs for government and businesses. The service dimension of tourism also potentially creates employment opportunities for women that otherwise may not exist.

Economic development through tourism is established not only by the stock of its built capital (for example, transport and energy infrastructure, water supply, and sanitation), or of its natural capital (that is, national parks and biodiversity), but also by its human capital (that is, skill, knowledge, education) and social capital, especially the connectedness of entrepreneurs to a destination. Therefore, tourist destination development can have important economic impacts on other sectors. The enabling role of tourism for business travel (that is, the role of hotels, hospitality, conference centers, and the tourism transport system) in facilitating business and trade networks is an often overlooked indirect contribution of tourism to economic development.

Employment

The employment opportunities generated by tourism have aroused substantial debate with respect to their true value to destination communities in comparison with other industries. Although a tourism-based economy can provide employment for people with limited training and skills, many of these part-time and casual jobs also pay low or minimum wages that may result in a population of working poor.

The relative value of tourism employment is also often contested because many of the jobs are regarded as being relatively low skilled. Although this has both advantages and disadvantages, tourism therefore provides opportunities for income generation in entry-level positions for those with low skill or language levels, thereby creating significant opportunities for migrants. Employment in tourism is also highly gender specific, especially when the empirical and emotional labor of hospitality is often regarded as women's work in many societies.

Another characteristic of employment in tourism and hospitality is the extent of variable demand over time and space. As a service industry, the tourism labor force has to be assembled at the point of consumption and also be sufficiently flexible to meet daily, weekly, and seasonal fluctuations. For example, at the microlevel, consumer purchase of lunch and evening meals leads to a high degree of part-time and casual employment in the restaurant sector to meet peak demand. The macro-level seasonal demand leads to substantial fluctuations in employment availability, which is often met by the hiring of employees from outside the destination area.

The extent to which seasonal tourism demand generates temporary migration and working-holiday flows, rather than use of local labor, is contingent on the location and the nature of tourism development, with a prime consideration being the capacity of labor to be transferred from other

sectors to tourism at periods of peak demand. For example, although tourism is economically significant in many rural areas, where peak demand for labor in agriculture is simultaneous with high levels of summer tourism demand, it can be extremely difficult to supply adequate labor from the destination region. In contrast, where peak tourism demand is in winter, as in some alpine areas, then agriculture and tourism may be much more compatible economic development mechanisms.

Seasonality

The phenomenon of seasonality is arguably one of the main issues in understanding tourism's potential contribution to economic development, because it affects not only employment but also tourism businesses. Seasonality is the result of the characteristics of the tourist-generating area and the destination. In terms of the generating area, key factors are timing of legislated holidays, especially

Tourists photograph lions resting in the Selous Game Reserve in the south of Tanzania in 2009. Most tourism growth is forecast for emerging economies such as those found in Africa and in the Asia-Pacific region, with 57 percent of international arrivals occurring in such countries by 2030. Tourism's presumed potential for poverty alleviation may not be realized, however, as research on the economic effects of the tourism industry in Kenya, Tanzania, and Uganda has found that most benefits go to those who are already wealthy.

school holidays, religious and cultural holiday conventions, and weather conditions.

Destination seasonality is strongly influenced by weather conditions and the overall resource availability for certain types of attractions, such as snow for skiing or the availability of particular scenery, as in the case of changing leaf colors for fall tourism in the northeastern United States. Although some forms of tourism, such as business travel, are affected by seasonal fluctuations in demand, seasonality affects nearly all aspects of tourism business and presents one of the greatest challenges at both a firm and destination scale.

Partial Industrialization

The nature of the tourism industry means that many sectors that make up tourism (for example, transport, visitor services, accommodation, restaurants, museums, art galleries, and attractions) have different business goals because they serve both tourists and nontourists. The situation in which the customers of many tourism businesses are nontourists is termed “partial industrialization,” and this is the condition by which only certain firms and agencies that provide goods and services directly to tourists are regarded as part of the tourism industry.

Partial industrialization is important for reasons including cooperation, management, policy, and strategy, as well as economic statistics. For example, the notion of partial industrialization reflects the statistical development of Tourism Satellite Accounts, which are now extensively used to measure tourism’s economic and, to a lesser extent, environmental impact.

From a strategic perspective, one of the consequences of the partial industrialization of tourism are its significance for tourism development, marketing, coordination, and network development. For example, although many segments of the economy benefit from tourism, only those organizations that perceive a direct relationship to tourists and tourism producers usually become directly involved in cooperative tourism development and marketing. Therefore, external inducements, such as promotion schemes established by government at no or minimal cost to individual businesses, or regulatory action such as compulsory business rating tax for promotion purposes, are often required before linkages can be established with those businesses

that do not normally regard themselves as being in the business of tourism. However, the significance of networks for tourism applies across all subsectors no matter what the size of the firm or sector. It is only in those limited numbers of firms that continue to offer package tours to tourists within their own vertically integrated business structures that the role of networks is downplayed.

The concept of partial industrialization highlights that the tourism industry and destinations can be framed as loosely articulated groups of suppliers who link together to deliver the overall trip and destination products, as well as knowledge transfer.

Three different main types of networks can be identified. First, innovative networks where businesses share complementary assets, such as airline alliances. Second, networks of businesses sharing in the marketing knowledge of specific customer segments. This includes the vertical and horizontal integration strategies of larger companies, as well as the knowledge management associated with special-interest tourism products, such as medical tourism, for which there are multideestination industry associations. Third, networks coordinating complementary assets at the destination level. This includes destination marketing alliances and promotion and the development of new products and innovations. Tourism businesses then strategically position themselves within such networks to leverage from innovation and future organizational configurations.

The contemporary tourism industry is characterized by a small number of large, often multinational firms with economies of scale, wide distribution, and a global network, taking a high-volume, low-profit approach, particularly in the aviation and accommodation sectors, and large numbers of small firms that are often niche-differentiated operators focusing on particular destinations or products, independent of external control and not influencing market prices.

Many destinations are therefore dominated by micro-businesses of fewer than five employees that are often owner operated. Such small tourism firms are often a significant tourism policy focus of governments and economic development agencies, especially in more peripheral regions that are undergoing economic restructuring and transition economies. Although such small businesses are often criticized by larger operators as not being

“real” businesses, particularly as their owners may be participating in tourism for lifestyle reasons, such firms are extremely significant because they play an important role in rapidly responding to peak tourist demand and rapidly diffuse income into the destination economy through strong backward linkages.

Criticisms

Tourism's contribution to economic development has been criticized because of its less positive environmental and social impacts, while, in some cases, its economic and employment contribution has not been as great as policy makers believed. For example, research on tourism in Kenya, Tanzania, and Uganda indicated that hotels, restaurants, and the transport industry provide below-average shares of income to poor households compared to other export sectors. In some cases, it has been suggested that tourism may be disproportionately beneficial to the already wealthy and fail to assist the poorest members of society who do not have the capital or language skills to cater to international tourists, thereby reinforcing already existing inequalities.

One of the difficulties in assessing tourism's contribution to regional development, and to poverty reduction and alleviation in particular, is that while tourism has been promoted in the economic development community for over 40 years, the mid- to long-term relative contribution of tourism to regional development strategies remains poorly evaluated. For example, in the LDC context there has been greater interest by international development agencies in advocating tourism and initiating projects than in the critical assessment of their consequences. These empirical weaknesses have only been reinforced by increasing awareness of tourism's contribution to climate and environmental change, and therefore concerns over its long-term economic contribution, particularly for those island, coastal, and alpine destinations that are most dependent on tourism.

Traffic Calming

In all facets of transportation planning, the automobile asserts its dominance. From highways to arterial and collector streets and down to local roads, infrastructure design has placed the automobile at the apex of the transportation hierarchy. Well-paved roads with wide lanes, along with incomplete or nonexistent sidewalks, crosswalks, and bicycle lanes, have resulted in a sprawling built environment.

Yet, until the 20th century, the design of communities was oriented primarily around the pedestrian. Characterized by mixed land use, a grid of connected streets, and moderately high densities, traditional land use patterns were noted for their connectivity and accessibility. As a result, these types of communities are deemed “walkable” in today's parlance.

Following World War II and beginning with the widespread construction of the suburbs and the interstate highway system in the 1950s, this walkable neighborhood design was increasingly replaced by dependence on the automobile. Cul-de-sacs were substituted for connector roads, blocks became larger, and land uses were separated by inflexible zoning codes. More than just discouraged, pedestrian activity became next to impossible. Where it

did occur, the dangers incurred by traversing the streetscape on foot were daunting.

Efforts to mitigate the risk factors associated with pedestrian travel are frequently associated with the concept of traffic calming. Encompassing a series of design principles, the primary objective of traffic calming is the reduction of automobile speed and volume along residential streets.

Traffic calming devices may fall under the following four broad categories based on their design. First, vertical deflections are elevated sections of roadway that force drivers to slow down. A common type of vertical deflection is the speed hump, which is a raised area in the roadway pavement extending across the entire road. Raised crosswalks and speed tables also serve as examples of vertical deflections. Second, horizontal deflections, a second category of calming, alter the street width to discourage through traffic and reduce traffic volume. Chicanes are a common approach to horizontal deflection and are created by building out curb lines. Roundabouts and traffic circles also serve as horizontal deflections on busier streets. Third, narrowings are roadway segments that are narrower than the overall width of the street. One example is the “neckdown,” which is created by narrowing the street and widening the sidewalk. Fourth and finally, speed zoning is a section of street with a lower maximum legal speed than the limit for the rest of the roadway.

Additional traffic calming devices include the following: bus bulb, a widening of the sidewalk at a bus stop location so that buses remain in the travel lane when stopped at the bus stop; pedestrian refuge, a small island placed in the center of a two-way street that separates traffic and enables pedestrians to cross the street in stages; and roadway color/texture, the use of materials that introduce surface texture to the roadway, such as paver stones, bricks, or stamped asphalt.

Goals of Traffic Calming

In all cases, reducing traffic speed serves as the ultimate goal. In determining whether a specific roadway has a speeding problem, the 85th percentile speed, or the speed below which 85 percent of all traffic travels, is typically utilized.

Additional objectives of traffic calming include protecting neighborhoods from unwanted through traffic and increasing road safety. As noted by John Laplante and Barbara McCann, minimal reductions

Unlike the speed bump, the speed hump, like the one shown here, is less aggressive and more often used in residential areas to slow traffic. Even small speed reductions can lead to substantially higher rates of pedestrian survival in accidents.

in speed can have profound impacts on safety. A pedestrian struck by a car traveling 20 miles per hour has an 85 percent survivability rate. At 40 miles per hour, the survivability rate for the pedestrian plunges to only 15 percent.

A reduction in speed for most trips around town would add only a few minutes to the length of the trip but could exponentially increase safety for all nonmotorized users of the roadway. In fact, an increasing concern of transportation planners is the effect of roadways on animal populations. Reducing traffic volume and flow not only protects pedestrians and bicyclists, it can also reduce traffic-related mortality rates for many animals that are put at risk by the built environment. Continued decentralized growth and suburban sprawl has extended the human-dominated landscape into previously rural environs. The benefits of traffic calming therefore include improvement of living conditions for all inhabitants of an area.

The historic precedent of present-day traffic calming dates back to the 1940s and 1950s, when street closures and diverters were used to control traffic. However, it was not until the 1991 passage of the Intermodal Surface Transportation Efficiency Act (ISTEA) that traffic calming received

national attention. Considered a landmark piece of legislation, ISTEA required transportation agencies to prove that there was no alternative to a project catering to cars before another road could be built.

Further, the act endowed states with the power to put federal funds where they are most needed. As a result, states could decide to transfer funds from highways to mass transit. Also, the provisions of the act required states to set aside a portion of their federal funds for use on community amenities, such as pedestrian or bike facilities. Thus, the singular dominance of the automobile was challenged through this historic legislation that was succeeded by the 1998 Transportation Equity Act for the 21st Century (TEA-21) and the 2005 Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU).

In addition to legislative support of traffic calming, the success of such programs is also dependent on public acceptance. Without the backing of the community in which the traffic calming is being implemented, these tactics may serve as a source of conflict. Traffic calming devices are also not guaranteed to improve conditions, as personal choices still take precedence over infrastructure changes. For instance, the construction of a raised crosswalk cannot guarantee that motorists will slow down or that pedestrians will cross in the crosswalk.

Several disadvantages have been cited in regard to installation of traffic-calming treatments. For example, snowplowing and street cleaning may be hindered, and emergency response time may be affected. Some motorists will choose to avoid roadways with calming devices, thereby increasing traffic on adjacent roads. Some traffic calming measures can affect drainage, and their construction and maintenance may be relatively expensive. Lastly, the noise of vehicles going over raised crosswalks or speed humps may disturb nearby residents, and emissions for a road calmed by speed humps may be higher than a noncalmed road.

Despite these concerns, the advantages of traffic calming associated with improved safety, reduced vehicular speed and volume, and improved quality of residential life is difficult to refute. As a result, an ever increasing number of communities are implementing traffic calming treatments to their roadways. These self-enforcing measures are particularly beneficial to nonmotorized users of the street and can deliver desired changes in travel behavior.

The total annual vehicle miles traveled in the United States increased nearly 40 percent between 1990 and 2010, and a staggering 169 percent since 1970. With Americans fast approaching 3 trillion vehicle miles traveled annually, there is an ever increasing need for roadways that accommodate all users, not just those in motor vehicles. A comprehensive traffic calming program and an integrated traffic management approach can substantially benefit all users of a roadway and return the streetscape to a more walkable form.

Traffic Congestion

Traffic congestion can be understood as the process by which the number of vehicles on roads exceeds their capacity. Congestion can slow down or stop the flow of traffic altogether, leading to longer and more unpredictable travel times, as well as a host of economic, social, environmental, and infrastructural costs.

The causes of congestion can vary, from site-specific contexts in which driver behavior or local circumstances may slow or impede traffic flow to broader, systemic conditions in which the number of vehicles using a roadway network consistently

exceeds its carrying capacity. In this light, traffic congestion has been attributed to low-density, automobile-reliant forms of development. It has garnered attention from multiple levels of government, as well as business and private-sector groups, non-governmental organizations, and advocacy groups.

Researchers argue that the costs of congestion are increasing. Longer travel times create additional financial costs for commuters, such as lost work hours, as well as gas and vehicle maintenance costs. Observers also note growing costs for specific industries, such as logistics and construction, as well as losses for municipal, regional, and national economies, resulting in part from the aggregation of costs from delays as well as the relocation of businesses to areas with lower levels of traffic congestion.

A number of other costs arise from traffic congestion. These include health and ecological problems related to greater concentrations of vehicle emissions, the possibility of increased accident rates, and mental stress on drivers and passengers. Municipalities and other levels of government also face growing infrastructural costs, as well as growing planning challenges because of unpredictable aspects of increased traffic congestion.

Responses vary but have increasingly reflected greater interest in regulating vehicle traffic and implementing taxes, tolls, and other revenue tools to pay for the maintenance and expansion of roadway networks. Technological tools have also been deployed to coordinate traffic management across larger geographic areas.

Congestion in Context

A growing number of researchers, policy makers, and industry groups have attempted to measure the rate and impact of traffic congestion. Methods vary, but, in general, traffic congestion is related to length of travel time and costs of delays (on individual vehicles, within specific industries, or across regional and national economies). Congestion occurs as roadway capacity is approached or surpassed. Roadway capacity itself is based on a “reasonable” amount of time in which a vehicle is expected to travel along a section of roadway, according to the U.S. Transportation Research Board.

A number of factors contribute to growing rates of traffic congestion. In particular, the number of vehicles on roadway networks is considered to be the most significant variable. In turn, this has been

linked to economic and population growth. Rising gross domestic product (GDP) growth rates over the past several decades, for instance, have been associated with higher rates of automobile ownership. Population growth, too, has contributed to a concomitant increase in car ownership and use.

In the United States, the number of vehicles grew from approximately 74 million in 1960 to more than 240 million by 2010, with the number of vehicles surpassing the number of drivers from the early 1970s onward, according to the U.S. Department of Transportation’s Federal Highway Administration (FHWA). The number of drivers increased from 84 million in 1950 (out of a total population of 180 million) to 220 million by 2010 (out of a total population of 309 million). Vehicle ownership rates and distances traveled by drivers have increased, while occupancy per vehicle has decreased over the past 40 years.

In the United Kingdom, the number of passenger cars per inhabitant has also grown, from slightly over one in three in 1990 to nearly one-half by 2009, according to data from the European Union. The number of registered vehicles grew from 4 million in 1950 to more than 34 million in 2009, according to the UK Department for Transport. These data align closely with rates for the broader European region, with higher rates of vehicle registration in western Europe compared with eastern Europe.

More recently, however, there are varying perspectives on the registration and use of vehicles in different jurisdictions. Citing the global economic crisis of 2007 to 2008, some observers have noted declines in vehicle registration rates, drawing connections with reduced incomes and rising fuel costs. In the United States, for instance, traffic congestion rose by 22 percent between 2012 and 2013, while in Europe congestion declined by 18 percent, according to the U.S.-based traffic technology firm INRIX.

Decades of growth in the numbers of vehicles on roadway networks (which in many jurisdictions have seen little to no expansion in recent years) have contributed to both the intensity and rates of incidence of traffic congestion. Some observers cite this lack of growth in roadway networks as a contributor to congestion, while others have drawn different conclusions, emphasizing the design of roadways and the form of urban and suburban development as more significant influences. Other, more localized causes of traffic congestion include

poor weather conditions, intersecting infrastructure networks (such as railway crossings), and poor construction and maintenance.

Roadway design may also contribute to congestion. Specific elements such as freeway-to-freeway interchanges, on-ramps and exit ramps, and lane reductions or mergers may intensify or cause bottlenecks. Bottlenecks from these particular components now contribute more to congestion than an overall lack of roadway capacity (through length or number of lanes), according to the FHWA.

Planners and policy makers are paying greater attention to the built environment and its relationship to traffic congestion. Automobile-based transportation planning, combined with low-density residential development, have been connected to one of the predominant forms of urban expansion over the past 50 years, leading to conditions of sprawl.

Measuring Congestion and its Costs

Increasingly, travel time reliability measures are used to determine not only rates of congestion but also to understand variations among seasons, during different times of the day (such as during peak and off-peak hours), and day-to-day variations. Two specific measures of congestion include the Travel Time Index and the Planning Time Index used by FHWA.

The Travel Time Index compares travel times for specific distances between peak and “free-flow” periods to help determine the average extra time required for peak-hour trips. The Planning Time Index is a ratio used to determine the total amount of time that should be allocated for travel to avoid arriving late 95 percent of the time (or one weekday per month). Congested hours reflect the average number of hours in which roadways are congested

A recent study of traffic congestion in Asian cities ranked several metropolitan Indian areas within the top 10 for worst traffic. It is estimated that 90,000 people die from road accidents every year within India; however in 2007, more than 130,000 people died on India roadways, overtaking China's similar high fatality statistics.

(that is, traffic moves at speeds below 45 or 50 miles per hour), often expressed per day or weekday.

Other measures of congestion include wasted hours, or time spent idling, and wasted fuel, or amounts of fuel lost while idling in traffic. These are often measured as a way to determine a series of direct and indirect costs associated with traffic congestion. Although estimates and interpretations of the costs of traffic congestion can vary widely, there appears to be a shared perspective across academic, government, and business observers that the negative effects of congestion are increasing—and will continue to increase without more direct forms of intervention to reduce or manage traffic volumes.

Time lost by drivers is one of the most prominent ways of measuring costs, as are fuel costs, and wear and tear on their vehicles. In 2011, urban Americans spent 5.5 billion hours in traffic (averaging more than a week per commuter), up from 1.1 billion hours in 1982, according to the Texas Transportation Institute (TTI). Traffic congestion led to nearly \$3 billion in wasted fuel (or 19 gallons per automobile commuter). The total costs of congestion rose from \$24 billion in 1982 to \$121 billion in 2011. These figures include lost time and fuel, as well as pollution costs.

In the United Kingdom, direct costs of congestion totaled more than \$6.4 billion, or more than \$700 per household, in 2011, according to an INRIX study produced for the Centre for Economics and Business Research. The same study noted similar household costs for France and Germany.

In Canada, direct costs can reach up to about \$3 billion annually, according to the Canadian federal transportation ministry. However, estimates vary widely, with some observers pegging direct costs for commuters in the Greater Toronto Area alone (the largest metropolitan urban region in the country) at \$2 billion to \$3 billion.

Industries particularly vulnerable to increased rates of traffic congestion include logistics, construction, agriculture, and retail and wholesale trade. In the United States, traffic congestion costs the construction industry up to \$23 billion a year, because of delays in project completion stemming from late material shipments and lost labor time. Congestion costs the trucking industry upwards of \$27 billion a year in wasted time and fuel.

Often, these increased costs are passed along in higher prices for consumers. For instance, in the

United Kingdom, INRIX research traced a rise in consumer costs resulting from shipment delays and lost labor totaling more than \$160 per urban household per year.

Aggregate costs of delays and lost time also affect municipal and regional economies. Some researchers have examined how traffic congestion may lead to greater costs for businesses as they relocate to more accessible locations, losing out on agglomeration benefits, paying higher wages to compensate for longer commute times, or facing declining productivity.

In the Greater Toronto Area, one study found that the region's economy loses more than \$2 billion a year from indirect costs of congestion. In the United States, the Department of Transportation estimates that congestion costs the national economy \$200 billion per year.

Emerging research on the health effects of traffic congestion reflects a range of additional costs. In one study by researchers at the Harvard School of Public Health, air pollution from congestion in 83 U.S. cities was cited for causing more than 2,200 deaths annually in 2010 (but predicting a decline to 1,900 annually by 2030), totaling about \$18 billion from premature mortality. Pollutants from traffic congestion have also been associated with premature births and low birth rates.

However, congestion studies in Europe and the United States have also predicted declines in pollutants over the next two decades, even as the numbers of vehicles grows, resulting in large part from improvements in fuel efficiency.

Longer travel times in automobiles have also been linked with reduced physical activity, which can lead commuters to greater risk for heart disease and diabetes. Stress and isolation have also been attributed to increased traffic congestion by the Ontario College of Family Physicians.

Drivers may also be at greater risk of being in traffic accidents, in part because congestion causes them to drive at uneven speeds in high traffic density. Nonrecurring congestion (due to temporary disturbances) is also correlated to 40 percent to 50 percent of accidents, according to the American Automobile Association (AAA).

Traffic congestion can also contribute to increased costs of other elements of urban infrastructure. Emergency response vehicles may face longer or more variable response times from congestion. As a

result, some municipalities have increased the number of fire or ambulance stations to compensate.

Spillover, or traffic infiltration, is also difficult to anticipate or manage. As main roadways or highways become congested, smaller roads see increasing amounts of traffic, as well as different types of traffic, as drivers seek alternatives. Conflicts can arise in municipalities that see a greater presence of transport trucks in residential areas, for example. The increases in both scale and complexity of roadway networks make it difficult for individual municipalities to address systemwide conditions.

Debates

A number of tensions have emerged among researchers and policy makers with regard to measuring, defining, and responding to traffic congestion. Some are related to debates over the effects of urban sprawl, while others address the emphasis on the automobile in research and responses. The Texas Transportation Institute (TTI), for instance, has issued a formal response to criticisms from Todd Litman, a planner with the Victoria Transport Institute, over its methodology and findings. The nonprofit organization, CEOs for Cities, also challenged the TTI for overestimating congestion costs and not addressing specific costs of urban sprawl in relation to transportation.

Responses

Part of the difficulty in responding to greater incidences of traffic congestion has to deal with temporal and spatial conditions. Congestion can be somewhat unpredictable or inconsistent, requiring greater understanding of peak road usage times and seasonal variation. As well, the effects of traffic congestion can extend beyond local or municipal boundaries and have unanticipated consequences in other road networks as drivers seek alternative routes. Cross-jurisdictional effects make it difficult to coordinate effective responses across varying levels of governments or among different public agencies.

Roadway expansion, through the extension or creation of new highways or roads, or the construction of additional lanes, may alleviate traffic congestion in the short term. Modifications to reduce impediments to vehicles may also improve traffic flow. However, many analyses show the prospects for reducing congestion through increased capacity are limited. Additional capacity can actually lead to more vehicles on roadways. (This is a result of latent

demand, which may be briefly alleviated through expansion.) Longer-term effects can be commuters moving farther away from their workplaces, increasing travel distances, and, eventually, leading to greater congestion at a later time.

Responses vary by region and level of government. However, a number of recent initiatives reflect greater efforts to integrate responses across jurisdictions, provide additional funding for roadway infrastructure (often through tolls, taxes, or other fees), and modify planning and development practices for urban metropolitan areas.

Transportation-specific revenue tools can include road tolls, fuel taxes, parking levies, and municipal or regional sales taxes. These are often developed with an eye toward recovering infrastructure costs directly from users themselves. The European Commission (EC) supports taxes and tolls among its member states to build and maintain trans-European infrastructure. Supporting principles of user-pay and polluter-pay, the EC has developed directives on vehicle and fuel taxes, as well as tolls and time-use charges for heavy-use vehicles, but not private automobiles, light commercial vehicles, or motorcycles. Member states have coordinated transnational networks for electronic use charges under this system.

In the United Kingdom, the city of London has introduced a congestion charge to be paid by most vehicles in the central city. Some exemptions are permitted, including cars that emit low levels of carbon dioxide as well as specific types of electric and hybrid vehicles.

The United States has more than 5,300 miles of toll roads and highways. During the 1980s and 1990s, the federal government renewed support for developing tolls as a means of funding the maintenance or expansion of interstate and other roadway networks during a period of reduced public spending. The U.S. Government Accountability Office is also considering allowing greater private-sector involvement in building and operating toll roads, although earlier projects in different states have had poor or mixed results. The GAO has also raised concerns over equity and accessibility, based on driver income levels and geographic location.

Types of toll roads can include specific express toll lanes or high-occupancy toll (HOT) lanes, in which vehicles with two or more occupants (high-occupancy vehicles) are subject to tolls to drive in special lanes. Variable rates may also be charged, depending

on time of day, for instance. As well, information and communications technologies facilitate the collection of use data and billing (electronic toll collection).

However, coordination among different levels of government is not always successful. In 2008, New York Mayor Michael Bloomberg failed to gain state approval for a congestion pricing plan in the city that would have funded public transit infrastructure.

In Canada, the federal government allocates a portion of gas tax revenues to cities. Although not geared specifically toward transportation expenses, the fund is meant to be directed to municipal infrastructure projects. Municipalities receive funds based on their population.

Governance arrangements have also emerged as a means of developing plans and funding strategies across municipal boundaries. In Canada, the Ontario provincial government has created a regional transportation authority responsible for planning and administering roadway and transit projects in the Greater Toronto and Hamilton Area, in conjunction with individual municipalities. In the province of British Columbia, the TransLink authority was renamed the South Coast British Columbia Transportation Authority and is now governed in part by mayors from all member municipalities of metropolitan Vancouver.

Other Approaches

Planners, researchers, and policy makers also emphasize the role of public transit in alleviating traffic congestion. Funding, however, remains a concern, given long-standing retrenchment in public spending and what some observers consider to be relatively high user fees that on their own cannot sustain a transit system's operating costs. In Toronto, debates over municipal and regional transit funding have seen opposition from local councilors who consider streetcars and light rapid transit vehicles as contributors to congestion.

A number of technical and technological tools have also emerged to predict, manage, and reduce traffic congestion. Transportation or travel demand management makes use of data to develop more efficient uses of transportation systems and provide alternative routes or modes. It may also incorporate education campaigns, incentives, or disincentives to shift commute times and modes of transportation. Similarly, intelligent transportation systems

incorporate advanced technologies to support transportation decision making and management. Active traffic management addresses traffic congestion specifically, relying on real-time data collection.

Driver education has also been cited as an important factor in mitigating traffic congestion (by reducing accidents and aggressive driving habits). Researchers from the University of California, Berkeley and the Massachusetts Institute of Technology have combined data generated through technologies such as the Global Positioning System and smartphone applications to establish relationships between driving habits and traffic congestion. Greater understanding of driving conditions on specific roadways can lead to more regionally based responses, spreading out traffic flows to avoid concentrating traffic in particularly difficult areas.

Traffic Control Devices

Traffic control devices (TCDs) are the familiar signs, marking, signals, and other devices located along a roadway that provide the primary means of communicating vital information to road users. TCDs use colors, shapes, symbols, words, sounds, and/or tactile information to communicate regulatory, warning, or guidance messages to road users on roadways and other type of facilities that serve vehicles, pedestrians, and bicycles. The messages provided by TCDs help the users of those facilities navigate the transportation network in a safe and efficient manner and provide for orderly movement.

TCDs have been a part of the surface transportation network from the earliest part of the automobile age. From their inception to the 1930s, these devices assumed a wide variety of appearances. In the late 1920s and early 1930s, state highway departments in the United States began working together to create a system of consistent, or uniform, traffic control devices that has been continually improved over the years.

The TCDs in use today provide a coordinated and effective means of communicating information to road users and promoting the safety and efficiency of the surface transportation system. Each country establishes its own practices regarding TCD characteristics. This article focuses upon the system of TCDs used in the United States.

The evolution of TCDs from an individualized design and selection process to a high-level uniform system occurred over many decades through the application of scientific principles, research, engineering experience, and policy-making actions. Today, decisions regarding the various aspects of TCDs are generally made by the governmental agency or private property owner having jurisdiction over the roadway, and these decisions are guided by the national authoritative TCD reference document, which is the *Manual on Uniform Traffic Control Devices*, or MUTCD. In order to appreciate how the MUTCD impacts TCD decision making, it is appropriate to first describe the various activities associated with TCDs and the types of TCDs before describing key aspects of the MUTCD.

Traffic Control Device Activities

While TCDs themselves are physical objects located near a roadway, there are many activities associated

with the process of placing them there. These activities include meaning (definition), design (appearance), selection (use), placement (installation), operation, and maintenance.

The meaning of a TCD defines its purpose, the message it conveys to road users, and the intended user response to the device. TCD meaning can be established through law, regulation, or traffic engineering standards. It is imperative that a TCD have the same meaning no matter where it is used.

The design of a TCD defines its appearance as it appears to road users. Design addresses such features as color, shape, pattern, layout of elements, size of elements, and overall size. In order to establish uniformity in how road users respond to TCDs, design aspects such as color, shape, and layout are standardized so that they appear the same in all situations. Individual design characteristics typically convey specific messages. An example is that red is used to indicate a stop or prohibitory message. A diamond sign shape indicates a warning of a potential hazard.

The selection of TCDs relates to the process of deciding whether it is appropriate to use a given device in a specific situation. The use of a device can range from a requirement at one end to a decision at the other end. The levels of use are identified below.

A TCD is required to be used if specific conditions exist at a location. An example of a required use is that a speed limit sign is required if the speed limit changes on the road. Warrants are criteria that identify minimum conditions that need to exist before a TCD can be considered for use. A device is required to be used if it meets the warranting criteria, but it should not be used if it does not meet the warranting criteria. Warranting criteria may be individual or combinations of factors such as traffic volume, speed, and crash history.

If a TCD meets the warranting criteria, or if there are no warranting criteria, the decision whether to use a TCD at a given location is typically an engineering decision that is made by an engineer (or other appropriately qualified individual). In making such a decision, the engineer considers a variety of factors to decide whether installation of the device will improve safety, efficiency, or other aspects of the roadway.

The placement of a TCD relates to where it is installed in relation to the roadway and the condition to which it is related. Placement criteria are

typically related to the three axes of distance indicated below:

- *Longitudinal*: The distance along the length of the roadway between the device and the condition to which it relates. Some devices are placed at the condition (such as a stop sign) and other devices are placed in advance of a condition (such as a curve warning sign).
- *Lateral*: The distance across the width of the roadway (including the portion beyond the paved road) where the device is placed. The placement can be a location within a particular lane or a distance off the roadway.
- *Height*: The height of a device is its distance above the roadway surface.

Not all TCDs are static and unchanging. For those that have a dynamic appearance, the operation of a TCD describes how the appearance of the device changes with time. The red to green to yellow status of a traffic control signal provides a common example of the operation of a dynamic TCD.

The maintenance of TCDs describes activities related to keeping TCDs performing in the intended manner. TCD maintenance activities include factors such as checking whether a device is missing or has been moved, whether it retains the intended appearance characteristics, and whether it operates as intended.

Types of Traffic Control Devices

The term *traffic control devices* refers to a large number of individual types of devices that can be used on or near a roadway to communicate with road users. The three most common types of TCDs are traffic signs, pavement markings, and traffic signals. Each of these types can be further divided into subtypes as indicated below. There are also less-known types of devices, such as channelizing devices and barricades. This list also describes the purpose of each subtype of TCD.

Traffic signs use words or symbols presented in a vertical plane to convey various types of messages. Regulatory signs inform road users of laws, regulations, or requirements that are in effect at a specific location or over a length of road. Regulatory signs are typically located at the point where the law, regulation, or requirement applies or changes.

Examples include Stop signs, Speed Limit signs, No Right Turn signs, and Keep Right signs. The most common appearance for regulatory signs is a vertically oriented rectangle with a black legend (or copy) on a white background.

Warning signs provide a warning of a potentially hazardous condition that may exist in or near the highway. Warning signs are typically located in advance of a potential hazard. Examples include Curve signs, Stop Ahead signs, and Low Clearance signs. The most common appearance for a warning sign is a diamond with black legend on a yellow background.

Guide signs provide navigational information such as the location of streets and highways, direction of travel, and location of various services. Guide signs can be located at a specific point (such as with a street name sign) or in advance of a specific point (such as an advance freeway guide sign). The most common appearance for guide signs that identify roadway locations is a horizontal rectangle with white legend on a green background. If the sign relates to services, the color combination is a white legend on a blue background. Guide signs related to cultural or recreational locations typically have a white legend on a brown background.

Changeable message signs (CMS) are a special category of sign that can present a message that changes with time. CMS can present regulatory, warning, or guide messages depending upon the needs at a particular location. Permanently installed CMS tend to be used on freeways to inform road users of travel times and road conditions. Portable CMS are used at specific locations for temporary conditions that may need to convey a message that cannot be presented in a static sign.

Pavement markings use patterns, colors, arrows, and words that are presented on the surface of the roadway (on the pavement in a horizontal plane) to regulate, warn, and guide traffic. Longitudinal markings define the location of lanes, the direction of travel within a lane, and restrictions on the ability to change lanes. Longitudinal markings use yellow to separate opposing traffic or define the left edge of the traveled way and white to separate lanes traveling in the same direction or define the right edge of the traveled way. Broken (dashed) longitudinal lines can be crossed while solid lines discourage or prohibit crossing. Examples of longitudinal lines include center lines, lane lines, and edge lines.

A pedestrian LED traffic light in New York City shows an orange hand signal to inform individuals when it is appropriate to enter the intersection. Some of these pedestrian crossing lights also have audible signals to assist those with special needs.

- Transverse markings extend across the roadway to indicate the point where a specific activity should take place. Transverse markings are white and typically use a solid line. Examples include stop lines and crosswalks.
- Word and symbol markings use arrows, words, and symbols to convey a specific message. These markings are typically white. Examples include lane user arrows, words such as ONLY, and the accessibility parking space marking.
- Traffic signals use changing color and shape displays to direct traffic to take a specific action or to provide additional emphasis to a warning message in a sign.
- Traffic control signals assign the right-of-way to conflicting approaches at an intersection. These signals use red, green, and yellow indications to indicate a stop, go, or caution action. Signal indications can be circular or arrow shaped. They can also operate in a steady or flashing mode. Each combination of color, shape, and mode has a specific meaning.
- Pedestrian signals inform pedestrians when it is appropriate to enter and not enter a roadway. The indications are a steady white walking man symbol, a flashing orange hand symbol, and steady orange hand signal.
- Lane-use control signals are placed over a lane to indicate whether the lane is open to travel in the direction from which the signal is visible. Displays include a down green arrow (okay to use lane), a yellow X (prepare to vacate lane), and a red X (lane is closed). Lane-use control signals can also be used to indicate that a lane is used only for left turn movements.
- Intersection beacons use flashing red or yellow circular displays to inform traffic approaching an intersection whether the vehicle must stop (flashing red) or proceed with caution (flashing yellow).
- Flashing beacons use flashing red or yellow circular indications in combination with a regulatory or warning sign to provide additional emphasis for the stop, speed limit, or warning message conveyed by the sign.

Manual on Uniform Traffic Control Devices

In the United States, the use of TCDs is regulated by the MUTCD. The U.S. Code of Federal Regulations (CFR) defines the MUTCD as the national standard for all TCDs installed on any street, highway, or bicycle trail open to public travel. Federal regulations require each state to adopt the national MUTCD or a state version of the MUTCD that complies with the national version (defined as substantial conformance).

While individual state laws vary in the language used, they generally require all TCDs within that state to comply with the MUTCD. Historically, the TCD principles presented in the MUTCD applied only to roads owned by governmental agencies but recent changes in the CFR and MUTCD have extended the application of the MUTCD to private property, as well.

The fact that the MUTCD is defined in federal regulations as a national standard makes it a legal document, and, in fact, it is the only major transportation engineering reference document that is so defined as a national standard. Failure to comply with MUTCD provisions is often a factor in tort liability lawsuits. In fact, a desire to reduce

tort liability exposure is often a motivating factor in complying with the MUTCD, because there is no other enforcement mechanism associated with MUTCD principles.

A concern over the potential of tort liability exposure is only a small factor in the desire to comply with the MUTCD. The TCD principles contained in the document are based on decades of experience in using TCDs and also based on scientific principles such as human factors (such as visibility and perception-reaction time), driver understanding, safety impacts, and operational efficiency. By using engineering experience combined with the MUTCD provisions, those responsible for roadways are working to promote safe and efficient movement of roadway users.

To use the MUTCD, a traffic engineer (or other appropriately qualified individual) must understand not only the legal status of the document but also how the organization and presentation of TCD principles establish different levels of mandate on their use. Users also need to understand how they can use their experiences with TCD effectiveness to impact the continued improvement of the MUTCD.

MUTCD Organization and Content

The 2009 MUTCD is divided into nine parts and each part is subdivided into chapters. Each section address specific devices. Parts 2 through 4 describe aspects of the three basic type of devices. Parts 5 through 9 describe how the three basic types of devices are used in specific types of applications. The stovepipe nature of MUTCD content corresponds with how the document is organized and how content in one part of the manual relates to content in other parts.

Within each MUTCD part, the text is categorized by a heading that indicates the level of mandate (requirement for use) associated with that text. Most of these categories have a specific action verb that also defines the level of mandate, and that has an established legal meaning. The categories and action words are listed below. One of the impacts of this structure is that the headings break up the flow of the information and can make it more difficult to read.

- *Standard*: A required, mandatory, or specifically prohibited practice. The verb *shall* is used in a standard statement

- *Guidance*: A recommended, but not mandatory, practice that is appropriate for typical conditions. Deviations are permitted when an engineering decision indicates such a deviation to be appropriate. The verb *should* is used in a guidance statement
- *Option*: A permissive practice that is allowed, but carries no mandatory or recommended implication. An option may modify a standard or guidance statement. The verb *may* is used in an option statement
- *Support*: An informational statement that provides only background information. Support statements do not establish any mandatory, recommended, or optional practice. Option statements cannot use the verbs *shall*, *should*, or *may*

MUTCD Ownership and Revision Process

The MUTCD is owned and administered by the Federal Highway Administration (FHWA), which is part of the U.S. Department of Transportation. Because it is defined as a federal regulation, changes to the document must be made using the federal rulemaking process.

Ideas for changes to the MUTCD are sometimes developed within FHWA, but are often recommended to the FHWA by the National Committee on Uniform Traffic Control Devices (NCUTCD), which is a private organization whose sole purpose is to develop MUTCD recommendations for FHWA consideration. The NCUTCD is sponsored by 20 organizations that represent a broad spectrum of transportation agencies directly responsible for TCDs and sponsors from other segments of the transportation profession. The typical steps involved in revising the MUTCD are listed below:

- A proposed change or changes to the MUTCD are developed by the FHWA, NCUTCD, or others.
- The proposed change(s) is published in the *Federal Register* and the public is provided an opportunity to comment on the merits of the proposed change(s). For the proposed changes that became the 2009 MUTCD, there were over 1,800 letters submitted to the comment docket and these

letters contained over 15,000 individual comments about the proposed changes.

- The FHWA evaluates the comments and identifies adjustments that should be made to the proposed changes.
- The FHWA publishes a final rule in the *Federal Register* that summarizes the public comments on the change(s) and describes the final decision on the proposed change(s). The final rule becomes effective 30 days after publication in the *Federal Register*.

States have several options for using the MUTCD within an individual state. Most states adopt the national MUTCD as the only TCD manual. Some states adopt the national MUTCD but also issue a state MUTCD supplement. A few states develop their own MUTCD.

The CFR requires that a state MUTCD or supplement be in substantial conformance with the national MUTCD. A state has up to two years to adopt any changes that are made to the national MUTCD, although in some of the states that use the national MUTCD, changes are automatically adopted at the time they become effective. Some states have TCD practices that vary from the national MUTCD and these are allowed to continue if they were established in state law before 2006. The yellow crosswalks that are used in California in school zones are examples of such a deviation.

Future of Traffic Control Devices

The TCDs that are in use today are largely the same as those that have been in use for over 40 years. Recent improvements in TCDs include advancements in controller technologies for traffic signals, use of light emitting diodes in signs and signals, improved retro-reflective materials, and other improvements.

One area of recent improvement that is not a TCD but that affects TCD use is the widespread use of in-vehicle navigation devices. These in-vehicle devices have reduced road user reliance on guide signs and may serve as a precursor to a future where in-vehicle messages may reduce the need for TCDs on some types of high-volume facilities such as freeways. However, traditional TCDs are expected to continue in service for the foreseeable future, although their performance and/or effectiveness may be improved through direct communication between vehicles and

TCDs, improved nighttime visibility, better management of pavement space to adjust movements by time of day, and active warnings of intermittent hazards.

Traffic Demand Management

Traffic demand management (TDM), otherwise known as transport demand management or mobility management (especially in Europe), is a term that refers to a range of actions (for example, policies, programs, and projects) that modify the demand

for transport infrastructure and services in either space or time in order to improve the efficiency of the transport system. The term is distinguished by actions that respond to increases in the demand for transport by adding to transport infrastructure or capacity (that is, supply management), such as extending roads, expanding airports, or increasing space for parking facilities.

The origins of TDM can be traced back to the 1970s when the oil crises of 1973 and 1979 prompted various attempts in the United States to increase the fuel efficiency of transport and reduce oil dependence. TDM was also seen as a way of addressing other economic and environmental policy issues of the time, such as reducing traffic congestion (and thereby helping increase economic productivity) and improving air quality, which had become increasingly important in the United States since the 1960s.

In the 1980s, TDM gained prominence because it was seen as a cheaper and more effective way of dealing with increases in motorization than building additional transport infrastructure. The expansion of existing transport infrastructure, especially in urban areas, was facing increasing difficulties due to the high price and limited availability of land for new infrastructure, the financial constraints of public authorities responsible for providing the infrastructure, and the additional “external costs” on society and the environment associated with the provision of new infrastructure (for example, noise, health, air pollution, and severed communities).

Interest in TDM continued to grow in the 1990s, particularly in Europe, when the underlying philosophy of transport and infrastructure policy experienced shifts in many countries, moving from a predominantly supply-based “predict and provide” approach toward a new realism in which there was greater recognition that, even if new infrastructure is built to accommodate the expected increases in transport demand, levels of traffic, congestion, and pollution can still worsen because there is a substantial latent demand for transport.

TDM encompasses a wide range of measures to influence whether, how, when, where, and how often people travel. TDM measures are mostly related to urban passenger travel rather than intercity travel or freight transport, although the concept is also applicable to these policy areas. Although building additional transport infrastructure or capacity

can technically be categorized as supply management rather than demand management, increasing the capacity of public transport infrastructure or infrastructure for “green” modes (for example, walking and cycling) is generally considered to be a form of TDM.

Benefits

As well as promoting efficiency in the transport system, a variety of claims are made about the wider social, economic, and environmental benefits of TDM, such as that it accomplishes the following:

- Promotes transport choice, particularly for nondrivers
- Reduces the environmental impacts of transport
- Increases the energy efficiency of transport
- Improves the efficiency of land use
- Reduces public spending demands for transport
- Improves public health by increasing walking and cycling
- Reduces congestion, thereby increasing economic productivity

There are various ways of categorizing the main types of TDM measures. The grouping of TDM measures that follows represents just one example of these categorizations.

Education, promotion, and outreach measures can be used to raise awareness, improve understanding, and build positive attitudes about alternative transport choices. Examples include personalized travel assistance, cycle training and education campaigns to promote specific transport modes, and promotion events for public transport or green modes (for example, car-free day, cycle-to-work week).

Regulatory measures can be used to influence the relative accessibility of different modes of transport. They can be employed either to increase the accessibility of certain types (for example, bus lanes, bus-only access restrictions, and high occupancy vehicle lanes) or to decrease the accessibility of other modes (for example, access restrictions for cars). These measures can be applied either indefinitely or just at certain times of the day, week, or year.

Economic measures can be used to make particular transport choices more financially attractive

than others. A range of different measures, both push and pull measures (that is, disincentives and incentives, respectively), are available for this purpose. Examples include fuel taxes, road user charges, parking charges, tax incentives (for example, for commuting by public transport), and subsidies (for example, bicycle purchase subsidies for employees).

Land use measures can be used to influence the density, diversity, or design of urban development, all of which are important in shaping local levels of accessibility and, as a consequence, can influence travel distance and modal choice. Specific examples of land use measures include street layout patterns (which influence an area's permeability for different modes of transport), park-and-ride facilities (which provide an alternative to car journeys), and car parking location and capacity (which influence the number of vehicles with access to an area).

Traveler information measures provide travelers with information about how to reach their destination by different modes (and combinations of modes), the travel time involved, the costs, and sometimes the environmental impacts of these options (for example, energy consumption or CO₂ emissions). These measures can also be linked to real-time travel information to provide travelers with suggestions for alternative routes, modes, or travel times in order to avoid congestion, road closures, or tolls. These measures include online trip planning, real-time roadside travel displays, and traffic condition information.

Information and communication technology measures includes a range of electronic applications (mainly Internet-based) that allow communication or transactions to take place remotely, which reduces or eliminates the need to travel. Examples include teleworking, Internet banking, videoconferencing, and e-government. There are ongoing debates about whether some of these measures (for example, teleworking or videoconferencing) really do lead to less travel or in fact actually increase the overall demand for travel.

Modal integration measures provide ways to reduce the barriers (both physical and economic) to multimodal journeys (that is, journeys involving combinations of modes or transport operators) in order to provide viable alternative options to car journeys. Examples include public transport tickets,

coordinated public transport timetables (using different operators and different modes, such as rail, bus, tram, and ferry), bicycle carrying facilities on public transport, and multimodal travel planning tools (for example, online trip planning).

Organizational measures include measures to create or support organizations, organizational structures, or organizational procedures that promote more efficient transport operation. One commonly encountered example is car sharing or carpooling, which provide a way to increase the occupancy of vehicles and fuel efficiency per passenger.

TDM measures can be applied at the national, regional, or local administrative level. In addition, TDM measures can be site specific. In the latter case, TDM measures focus on managing travel demand at a certain location (for example, an office development, school, concert venue, sports arena, or hospital). In some countries (for example, Germany, Ireland, Sweden, and the UK), approval of planning permission for certain types of development is contingent on preparing a mobility plan that often contains a package of TDM measures.

While there is clear awareness among the majority of travelers about the environmental impact of their actions, their willingness to change behavior is often low because of a mixture of individual and social interests. A well-integrated set of TDM measures is needed to encourage these behavioral changes.

Traffic Detection Systems

Various vehicle detection systems are used to sense local traffic at a particular defined location, to gather and analyze aggregate data for that location, and to engineer or control traffic in that location. Intrusive detectors must be embedded within the roadway while nonintrusive detectors are placed adjacent to or above the roadway.

Researchers, traffic engineers, and policy makers utilize data gathered from vehicle detection systems for a variety of functions. Such data is also a key component in the development of new intelligent transportation systems (ITS) that have arisen to meet the challenge of expanding surface transportation capacity while mitigating cost and environmental effects.

Developed nations such as the United States have large and increasingly congested surface transportation systems. Industrialization, urbanization, suburbanization, the development of interstate highways, and the rise of an automobile culture are key causal factors. Surface transportation demands are expected to continue to increase in the foreseeable future, meaning increased system capacity is essential to traffic engineering, future roadway construction, and congestion reduction programs such as traffic calming.

Technological developments in the fields of telecommunications, computing, and information technology have made revolutionary advances in vehicle detection systems possible while older, time-tested methods with large experiential databases remain in wide usage.

Types of Vehicle Detection Systems

Vehicle detection systems are broadly characterized by whether they rely on sensors that require

placement within the road surface (known as intrusive systems) or do not require roadway embedment (known as nonintrusive systems).

Intrusive vehicle detection systems in use employ a variety of sensor types, including pneumatic road tube, inductive loop, piezoelectric, bending plate, load cell, capacitance mat, weigh-in-motion (WIM), magnetometer, and magnetic sensor systems, while nonintrusive systems in use include microwave radar, passive and active infrared (or laser radar), ultrasonic, passive acoustic array, and video image processors.

Historically, most vehicle detection systems are infrastructure rather than vehicle based. Pneumatic road tubes record the number of vehicles passing a particular location. Inductive loop detectors are one of the oldest and most common of the vehicle detection systems in use. Various shaped loops of insulated wire are embedded within the pavement, creating a magnetic field that detects passing vehicles. Inductive loop systems range from simple to more complex and may collect data in single or multiple lanes of traffic and from vehicles traveling at varying speeds. They provide data such as vehicle counts, vehicle speeds, vehicle length and weight, and distance between vehicles.

Two-axis floodgate magnetometers obtain vehicle data through measuring vertical and horizontal changes in the Earth's magnetic field. They are primarily used in construction zones, bridge decks, and viaducts where loop detectors are not feasible. Magnetic detection systems utilize a wire coil that measures certain changes in the Earth's magnetic field.

Microwave radar uses the transmission of microwave energy, while active infrared uses the transmission of infrared energy. Two common types of microwave radar in use are continuous wave (CW) Doppler radar and frequency modulated continuous wave (FMCW) radar. Passive infrared systems, which do not transmit energy in themselves, rely on the detection of energy transmitted from passing vehicles, the roadway, and other variables to gather data. Ultrasonic systems measure reflected waves from the transmission of ultrasonic sound energy.

Acoustic systems use the passive detection of sound energy or audible sounds to detect vehicles and measure their passage and speed. Video vehicle detection systems employ video cameras installed above or adjacent to roadways. Video image processors digitize and analyze the images to produce

vehicle and traffic data. Uses include traffic flow measurements such as lane occupancy and vehicle speeds and counts, as well as automatic license plate recognition and automatic incident, stopped vehicle, or wrong-way vehicle detection.

The various vehicle detection system types each have their own combination of strengths and weaknesses, which traffic engineers must take into account when choosing which system to install. Lane closures are required for the installation and/or maintenance of certain vehicle detection systems, including inductive loop, magnetometer, active infrared, and video image processors that are mounted above as opposed to alongside roadways.

Many vehicle detection systems can damage roadways or decrease road life span if improperly installed. Inductive loop, active and passive infrared, ultrasonic, and video image processor systems are also themselves vulnerable over time to damage from the passage of traffic and environmental conditions such as temperature extremes. Magnetic and magnetometer-based systems are less vulnerable to traffic stresses in the long term. Systems such as microwave radar, active infrared, ultrasonic, video image processors, and some models of acoustic arrays can provide data for multiple rather than single lanes of traffic.

Different types of vehicle detection systems have varying degrees of accuracy, may require the installation of multiple detectors in certain locations, and may have difficulty detecting stopped vehicles, stop-and-go traffic in heavily congested areas, or large numbers of vehicle classifications. Conditions such as vehicle shadows, extreme weather, fog or wind, dirt, and the transition between day and night can impact video camera lenses. Those less sensitive to inclement weather include inductive loop, magnetometer, magnetic, microwave radar, and acoustic.

Vehicle Detection Systems Data

Selection of vehicle detection system type, placement of vehicle detectors, and resulting traffic controller settings, such as traffic-signal timing, are determined both by analysis and the judgment of traffic engineers based on roadway or intersection type and by whether there is a high- or low-speed vehicle approach. Vehicle detectors are strategically placed along the roadway or other area to be measured, usually within the determined center of traffic flow. Various types of vehicle detection systems are

used either as single systems or as integrated systems combining several types of detection technology.

Vehicle detection systems gather data on such basic traffic variables as presence, speed, headway, gap, vehicle classification, weigh-in-motion (WIM), volume, and occupancy (measured as the percentage of time the vehicle is stationed over the detector). The latter two are the most commonly measured and used variables in the field of traffic engineering. Traffic engineers use the data obtained from vehicle detection systems to design traffic control and calming measures, such as traffic signal control. Data is also used to provide traveler information services.

Traffic engineers introduced ITS in the late 20th century to increase transportation system capacity without widening existing roadways or building additional roadways. The United States adopted its federal ITS program in 1991 under the auspices of the Intermodal Surface Transportation Efficiency Act. An enhanced emphasis on transportation security in the wake of terrorist attacks targeting transportation modes such as aircraft and mass transit has also heightened interest in ITS. Vehicle detection systems are an important component of ITS development because they are one of the primary data collection methods in use by ITS.

ITS relies on a combination of both infrastructure- and vehicle-based vehicle detection systems to gather traffic data. Traffic data obtained through vehicle detection systems aid in the reduction of traffic congestion, improvement of public safety, greater public access to traffic information, cost efficiency of transportation systems, and environmental impact mitigation. New technological developments such as microchip, wireless communications devices such as Bluetooth, RFID (radio frequency identification), and intelligent beacon sensing promise to continue to improve vehicle detection systems and their application to ITS.

Traffic Detection Technology

The U.S. surface transportation system consists of millions of miles of roadways that support trillions of passenger and freight miles each year. With transportation volumes increasingly rising, more capacity demands are being placed on the transportation infrastructure and systems in the United States. One approach to accommodate the growing capacity needs is to add infrastructure in the form of new roadway miles. An alternative solution has been to expand capacity through efficiency improvements throughout the existing transportation system.

The efficiency-improvement approach is largely focused on intelligent transportation systems (ITS) technologies that are designed to enhance public safety, reduce traffic congestion, improve access to travel and transit information, generate cost savings for agencies and operators, and reduce environmental impact of transportation activities. The ITS technologies used for traffic detection and surveillance utilize sensor, communication, and traffic control technologies to provide important data on the presence, count, speed, class, gap, headway, occupancy, weight, and link travel time of vehicles. The data is used to help optimize traffic planning, design, control, and management.

Primary Types of Traffic Detectors

Traffic detection systems rely on their ability to sense traffic, which is accomplished through the

use of one or more detector types. The two main types of traffic detectors are known as pavement-invasive detectors, which include inductive loop, magnetometer, and magnetic detectors, and non-pavement-invasive detectors based on microwave radar, active or passive infrared, ultrasonic, acoustic, or video image processor technologies.

Pavement-invasive detectors refer to devices that are installed directly onto the pavement surface, into grooves or holes cut into the road surface, under the surface of a roadway by means of tunneling, or anchored directly onto the pavement surface.

Non-pavement-invasive detectors encompass above-ground sensors that are mounted above traffic lanes or on the side of roadways to monitor multiple lanes of traffic at numerous angles. Like subsurface sensors, the above-ground devices are used to measure vehicle count, presence, and passage, but they have the added benefit of also being able to provide information about vehicle speed, vehicle classification, and multilane traffic volume and flow.

Pavement-invasive detectors. The most common traffic detection technology is inductive loop. It consists of one or more turns of insulated loop wire wound in a shallow slot carved into the road surface pavement. Loop detectors come in a multitude of shapes and sizes. Various configurations can be used based on the area under surveillance, the types of vehicles to be detected, and the objective of the data collection, such as counting vehicles or measuring speed. Inductive loop detectors are insensitive to most inclement weather conditions and have a high degree of accuracy, especially regarding vehicle count and occupancy measurement. However, inductive loop installations are subject to temperature and traffic stresses and often require multiple detectors to effectively monitor a specific location.

Another popular pavement-invasive detector type is a magnetometer. These types of detection devices measure changes in both the latitudinal and longitudinal components of the Earth's magnetic field. Magnetometers are especially useful for assessment on bridge decks and viaducts, where the underlying steel support structures tend to interfere with loop detectors and can be weakened by the embedded loop wire. Magnetometers also are appropriate for traffic detection related to temporary installations in construction zones. Like inductive loop installations, however, magnetometers

are susceptible to temperature and traffic stresses and may require multiple installations to effectively monitor a location.

Magnetic detectors are made up of a coil of wire with an extremely permeable core, a technology that helps measure changes in the lines of flux of the Earth's magnetic field. Since this type of detector can only sense vehicles that are moving faster than a specified minimum speed, they are not appropriate for detecting vehicle presence. However, magnetic traffic detectors are useful in situations where the road surface cannot be compromised or where deteriorated pavement or frost activity has resulted in breakage of inductive loop wires.

Pneumatic road tube sensors deliver a pulse of air pressure through a rubber tube when a vehicle's tires pass over the tube. The burst of air pressure closes an air switch, producing an electrical signal that is transmitted to a software program that analyzes vehicle count data. This type of detection device is installed perpendicular to the flow of traffic to provide short-term traffic counts, including vehicle classification by axle count and information about vehicle spacing. Some models calculate vehicle gaps, intersection stop delay, stop sign delay, saturation flow rate, spot speed as a function of vehicle class, and travel time when the counter is utilized in conjunction with a vehicle transmission sensor. Pneumatic road tube sensors are quick to install and are typically low cost and simple to maintain. The tube sensors are subject to wear, weather, and high-volume inaccuracy of axle counts.

Piezoelectric sensors are another type of pavement-invasive detection technology. Piezoelectric is a specially processed material that converts kinetic energy to electrical energy. Piezoelectric sensors are constructed using a coaxial with a metal, braided core element, and piezoelectric material surrounded by a metal outer layer. During the manufacturing process, the sensor is subjected to an intense electrical field that polarizes the piezoelectric material.

The material is used to generate voltage when subjected to mechanical impact or vibration that is proportional to the force or weight of the passing vehicle. Piezoelectric sensors are used to classify vehicles by axle count and spacing and, when multiple sensors are activated, to measure vehicle weight and speed. These types of sensors are commonly used as part of weigh-in-motion (WIM) systems (see below). They are unique in that they

gather information on vehicle tires passing over the sensor instead of on the passing of a vehicle, providing highly accurate differentiation of individual vehicles for precise counting. Once installed, the cost of piezoelectric sensors is only slightly higher than inductive loops, but they offer more information regarding vehicle speed, classification, and weight. Disadvantages include failure due to poor road surfaces or vandalism and sensitivity to pavement temperature and vehicle speeds.

WIM systems are used to estimate the gross vehicle weight of a vehicle, down to the proportion of weight carried by each wheel assembly, axle, and axle group. The information is used for highway planning, design, and safety enforcement. Specifically, WIM systems provide highway planners and designers with time and date of traffic volume, speed, vehicle classification based on number and spacing of axles, and the equivalent single-axle loading that heavy vehicles place on pavements and bridges.

The heavy-truck axle load data are used by motor vehicle enforcement agencies to plan enforcement activities. Accuracy of WIM systems is based on vehicle dynamics, such as suspension and driver activity; pavement composition and integrity, including surface texture and condition anomalies; and inherent system variances due to calibration and technology functions.

Non-pavement-invasive detectors. Microwave radar technology is not pavement invasive. It detects traffic presence, flow, and speed by transmitting microwave energy toward the roadway. Frequency modulated continuous wave radar is used to detect vehicle presence, while continuous wave Doppler radar detects vehicle flow and speed. It can be used for multiple-lane operation and is largely insensitive to inclement weather. Some radar-based detection systems are hindered by steel structures found in some large bridges.

Infrared detection is a widely used approach to traffic surveillance for data collection. Active infrared technology transmits infrared energy from a detector and measures the waves that are reflected back. By transmitting beams, active infrared technology provides for accurate measurement of vehicle position, speed, and class. Passive infrared technology does not actively transmit energy but detects energy from vehicles, roadways, and other objects as well as energy from the sun reflected off those

materials to provide an accurate measurement of vehicle speed. Detection devices that use infrared technology are more sensitive to weather conditions and require periodic maintenance, such as lens cleaning, that necessitates temporary lane closure.

Ultrasonic detectors transmit ultrasonic sound energy waves. They measure the distance that the reflected wave travels to determine vehicle presence, count, and lane occupancy. Ultrasonic devices can detect across multiple lanes of operation and are capable of detecting over-height vehicles, but large pulse repetitions may degrade occupancy measurement of moderate-speed vehicles on freeways.

Acoustic technology is used to measure the presence, passage, and speed of vehicles through passive detection of acoustic energy, or sounds created by vehicle traffic. It is largely impervious to the effects of precipitation and can operate across multiple lanes. On the negative side, cold temperatures and significant background noise may reduce vehicle count accuracy from acoustic detection sensors.

Video image processors use video cameras to detect traffic. The resulting images typically are digitized and converted into a broad array of traffic data. The main advantage of video detection is that it can measure traffic over a wider geographic area by linking information from multiple cameras at different locations, as compared to measurement at a single point provided by inductive loop sensors and other pavement-invasive detectors. On the other hand, the performance of video image processors can be affected by weather conditions and camera motion, and they involve more difficult installation and ongoing maintenance.

Cost Considerations

The total cost involved in using traffic detection technologies varies widely, based not only on the type of device but also on the time and expense needed for initial installation, ongoing maintenance and repair, and appropriateness for meeting the data collection needs of the transportation system.

Installation costs for inductive loops, for example, should be calculated to include expenses needed for technicians to prepare the road surface before embedding the sensors. Similarly, the costs for installing infrared sensors should take into account the expenses tied to preparing the structure on which the sensor will be mounted. In addition, there

may be costs tied to traffic lane closures required for traffic detection system installation.

Total costs for traffic detection systems also depend on the frequency and intricacy of ongoing maintenance and life cycle repairs. Less expensive devices may end up being less cost effective in the long run if they require repeated attention or replacement compared with devices that may be more expensive up-front but offer cost benefits in the long term from a reduced need to fix or replace.

The number of traffic detection devices needed to meet surveillance and data requirements also comes into play when determining total costs. For example, numerous inductive loops are needed to cover a multilane, multizone area that could be covered with just one video image processor.

Traffic Engineering

A branch of civil engineering, traffic engineering uses the techniques of engineering to plan transportation features that result in well-managed traffic flow. Civil engineering is the parent of most non-military engineering disciplines and is concerned with design and construction, especially of public works and infrastructure. The concerns of traffic engineering overlap with other types of

civil engineering, particularly highway engineering, transport engineering, and pavement engineering. While other engineers engaged in the process are responsible for planning the infrastructure of a transportation system, such as a bridge or a new road, traffic engineers plan the traffic control and management devices and features of that system.

For instance, a traffic engineer's area of concern would include the traffic signals and signs on a transportation route, and possibly modifications to speed limits, as well as traffic control measures such as speed bumps, traffic lights, road surface markers and lane markers, sidewalks, crosswalks, bicycle lanes, high-occupancy vehicle (HOV) lanes, and other features.

There is an element of traffic forecasting in the traffic engineer's job. Traffic engineers are involved with the planning of new transportation projects because their expertise allows them to estimate the traffic impacts of proposed changes, such as the effect on traffic through adjacent neighborhoods and streets of a new outlet mall, or the amount of traffic a bridge can be expected to see in a given amount of time and what that says about the proposed time frame of scheduled repairs or preventive maintenance work. Traffic engineers also present estimates about short-term impacts on traffic (for example, from construction, road closures, flooding and other weather impacts, or special events resulting in increased traffic flow) and propose solutions (for example, detours, reroutings, lane closures, and plans for pedestrian traffic).

They may also make recommendations about traffic control during accidents or brief construction (such as utility work, in which the work site continually moves over the course of the day, rather than blocking off a specific spot for a longer period of time), and what sort of traffic control methods (for example, an on-site traffic controller, flagger, or police officer, or mobile signs and other equipment) should be used. Construction traffic control is sometimes outsourced to dedicated companies, the larger of which may engage the services of a traffic engineer for consultation.

Traffic engineers may also consult with urban planners and state and municipal leadership in preparing evacuation routes in cities prone to natural disasters, making them necessary, such as in the hurricane-prone parts of the country. The New Orleans evacuation route, for instance, must take

Traffic engineering projects like this complex intersection may make use of findings on high crash rate locations and countermeasures to reduce crashes. Traffic engineers often work in conjunction with computer and electrical engineers.

into consideration the limited number of routes out of the city (which is surrounded by water) and the possibility of street flooding in the lower-lying areas. The increased use of computers and sophistication of specialized software have amplified the role of civil engineers in urban planning, because computers can handle the data and calculations necessary to forecast the possible results of various options.

Modern transportation systems increasingly provide the opportunity to supply traffic engineers with data for their work. Sensors provide better and more accurate traffic flow information than was available in the past, including not only the number of cars using a route but their average speed, the frequency of lane changes, and changes to traffic flow over the course of the day. Sometimes traffic flow information can be cross-checked against accident statistics in order to make suggestions to improve safety.

Dynamic elements can also be incorporated into road infrastructure, such as electronic traffic signs that can warn drivers of congestion or accidents. In some municipalities, dynamic lanes are used, changing the directionality of a lane of the street according to the time of day in order to respond to

traffic flow (typically following commuting patterns so that more lanes lead workward in the morning and homeward in the evening).

Some traffic engineers are employed as safety engineers, incorporating not only traffic information into their work but driver psychology. These engineers collect traffic and accident information to look for patterns, and identify areas or times in which accidents are disproportionately common, or about which driver complaints have been registered. The engineer's safety recommendation report will include both possible solutions (and an analysis of the cause, if it was not previously known) and cost-benefit analyses, as well as an analysis of the possibility that the solution will merely "squeeze" the problem elsewhere. Another problem traffic engineers seek to prevent is severe or recurring traffic jams or gridlock. It is assumed that, in some cases, this is unpreventable, but congestion can be managed, and the position of lanes, on-ramps, and exits can help limit the effects of congestion.

Traffic engineers working for transit companies help determine the potential or probable ridership of a route and plan the best locations for bus or train stops, as conditions permit. They can also help estimate bus dwell time—the time spent at any given stop, as a result of passengers embarking or disembarking—and the effects of traffic congestion and other traffic conditions on route scheduling.

Traffic engineering overlaps with transport engineering, which plans and designs transportation facilities for the transportation of passengers and goods, including the subdisciplines of aerospace engineering; air transportation engineering; highway engineering; pipeline engineering; waterway, port, coastal, and ocean engineering; and urban transportation engineering.

Both traffic and transport engineering are critical to urban planning and necessitate an awareness of political factors that impact the work at hand. They also both rely on an urban transportation forecasting model to forecast transportation use and traffic effects, based on what can be known or estimated about automobile ownership, land use, mode choice, route assignment, trip generation, and trip distribution.

While transport engineering is tasked with the design and construction of a highway, traffic engineering determines the capacity it will need.

Traffic engineers also assist in the planning of new major airports, in determining their best placement, the best way to adjust the highway system to accommodate them, and the effects on traffic patterns not only of passenger cars but of any bus routes and taxis.

Traffic engineering plays a role in pavement engineering, which is concerned with constructing asphalt and concrete pavements and their use in streets. Accurate traffic data tells a pavement engineer the type and amount of use a given paved surface can be expected to experience and how often repairs are likely to be needed, as well as which times of day repairs can be scheduled in order to reduce their impact on traffic flow.

Traffic Flow

Conventionally, traffic flow is considered to be the movement of motor vehicles along roads. The theory and principles developed for this can, however, be used for the movement of any discrete autonomous units along a road that are not subject to external time-tabling or control (for example, walking between and within terminals at an airport, cyclists on bikeways, etc.). For the purpose of this article, only motor vehicles on roads are considered. The impact of different kinds of vehicles on different roads is also discussed.

Analogies

In certain circumstances, traffic flow has similar characteristics to fluid dynamics. This is especially true for freeways, where the majority of vehicles are passenger cars with similar dynamic characteristics. Freeways are also designed to provide the smooth access and exit of motor vehicles from traffic streams. On freeways, there can be streamlined flows when traffic volumes are under road capacity and traffic is moving at nearly constant speed. As in fluid dynamics of liquids in a pipe, the traffic nearest the side flows more slowly than the traffic in the center of the road.

Turbulent flows occur when traffic volumes approach road capacity. This leads to shock waves caused by minor disturbances, such as a vehicle stopping on the road edge. At traffic volumes close to road capacity, such disturbances cause traffic to come to a halt randomly; it then starts again flowing freely, until it comes to another halt.

For all other roads, with mixed traffic mixed use (for example, roadside parking, bus stops, and others), traffic flow is more like Brownian motion—random and difficult to model, except at a macro scale. Nevertheless, traffic flows on such roads are important because they lead to and away from major roads like freeways. So, there is little point in having a freeway if its feeder and distributor roads are at a standstill. This will cause traffic to back up the freeway and bring it to a halt, with a zero flow.

Measurement and Impacts of Vehicle Types

Historically, traffic flows were measured manually and recorded on paper charts. Two main methods were developed: static roadside and “moving car,” the latter also determining the average traffic flow speed. Today, there are many remote or telemetric methods to capture real-time traffic flows. Some of these methods include magnetic loops in the road surface, which can also be used to determine vehicle speeds; closed-circuit television (CCTV) with vehicle-recognition software; and radar, among others. When coupled with software, not only can traffic volumes be recorded, but also traffic problems predicted, which can be used to trigger automatic control systems or alert traffic control staff.

The biggest impact on traffic flow is the mixture of large- and private-car-sized vehicles. Determining this can help planners and engineers get a better understanding of the mechanics of traffic flow.

This has led to adoption of a standard unit to represent traffic flows, the passenger car unit (pcu). This models the impact on traffic of a single passenger motor car. All other road vehicles can be represented in pcus. So, a rigid bus is 2.5 pcu, an articulated truck 4 pcu, a motor cycle 0.5 pcu, a pedal cycle 0.25 pcu. By this means, a heterogeneous traffic stream can be represented and measured in standardized (pcu) units.

Capacity, Speed, Volume, and Flow Relationship

Capacity is the theoretical ability of a road to carry traffic. A freeway lane can theoretically carry a maximum flow of 1,200 pcu per hour. An urban mixed-use road can carry a maximum of only about 800 pcu per lane per hour. Volume is the actual number of vehicles flowing along the road, which, by definition, is less than the capacity.

Traffic flow speed interrelates with volume. Obviously, if the traffic speed is zero, then the volume is zero, because there is no flow. As traffic speed increases, the volume increases, until it reaches a maximum on freeways at between 30 miles per hour (mph) and 40 mph (50 to 65 kilometers per hour, or km/h). After that, faster traffic flow speeds progressively reduce volume. The reason for this is that braking distances are a square of vehicle speed, so drivers leave progressively longer safe stopping distances between vehicles as traffic speed increases.

Measures to Improve Traffic Flow

Henry Barnes, one of New York’s former traffic commissioners, is reported to have said when visiting London in 1955 that he could sort out the traffic problems with a bucket of white paint and a brush. His point, which is still valid, is that measures to organize and manage traffic flows, in particular to minimize vehicles weaving between lanes, improve both flow and volume. To this end, effective and advanced signage allows drivers to maneuver in good time and smoothly, and therefore avoid creating perturbations in the traffic stream, which can create dangerous shock waves.

On urban roads, one-way streets have a greater traffic capacity than two-way. The reason for this is that traffic in opposite directions takes more space to pass than traffic going in the same direction. Many cities have therefore created complex networks of one-way streets. Often an additional traffic lane can

be created by converting from two-way flow to one-way, such as four lanes into five lanes.

Categorizing roads into “main” and “other” allows parking to be banned on main roads, greatly improving traffic flows, and restricting parking to other roads and off-road sites. The improvement in traffic flow on main roads would then be a result of both the release of parking space for moving traffic and the removal of stopping and reversing (parking) vehicles disturbing the smooth flow of other traffic.

Most cities use traffic signals to control safely the movement of opposing streams of traffic at intersections. Originally, such signals were on a fixed-time regime, usually adjusted to give the main road more time than the side road(s). At times of low volumes, this leads to traffic waiting for a green while there is no traffic crossing. This frustration for drivers was overcome by the use of vehicle-actuated signals. A pneumatic tube across the road is depressed by approaching vehicles, and when enough have arrived, the signal turns green.

This is fine for isolated intersections that are far enough apart not to interfere with each other's traffic flows. For road networks with close intersections, arranging the signals to work in harmony improves traffic flows. One way to do that is to organize groups of vehicles into “platoons” and then treat each platoon as a unit of traffic. By this means, intersection capacity can be increased when the signals are coordinated with platoons in opposing directions crossing in a synchronized manner. This should also lead to every platoon being able to pass successive intersections without stopping, with “green wave” signal coordination.

Pioneering studies on “area traffic control” were undertaken in Glasgow, Scotland, in the 1960s, where the green waves were set using historical traffic flow data. Today, with more powerful computers, the green wave can be adjusted in real time from contemporaneous traffic data, optimizing volumes and minimizing vehicle delays. One of the experiments undertaken in Glasgow was to answer the question how long it took drivers to adjust to different green wave speeds. The answer was about two weeks. Immediately after a green wave speed was changed, traffic flows were turbulent. This turbulence decreased with time and after two weeks, flows were as streamlined as they had been before the change of green wave speed.

Finally, metering traffic onto the critical road network or freeway allows traffic to flow smoothly and delays to be transferred to feeder roads. This metering requires the traffic on the main road to be monitored to identify gaps in traffic flows, allowing traffic on from ramps. When traffic on the main road approaches capacity, before flows become turbulent, traffic from side roads is stopped until the volume on the main road reduces, and free flow conditions are restored.

This metering can also be coordinated with advisory operating speed on the main road. When traffic at 60 mph (95 km/h) approaches the maximum capacity, the advisory speed can be reduced to 50 mph (80 km/h). This increases effective capacity.

Measures to Manage or Restrict Traffic Flow

Most roads do not exist solely for the movement of motor vehicles. Many roads have pedestrians, shops and commercial premises that require the delivery or collection of goods, and parking to visit properties along the road. While one-way traffic networks improve motor vehicle flows, they create problems for other road users, principally pedestrians, who find crossing roads carrying large flows at fast speeds difficult and dangerous.

Traffic also causes environmental problems of air pollution and noise, both of which make working and shopping in the areas near busy roads less attractive. This has led in the last 20 years to cities adopting progressive measures to reduce central business district (CBD) traffic flows, encouraging motorists to use more environmentally friendly modes, such as buses or light rail. Road space can then be reallocated to more environmentally benign uses, such as bike and bus lanes, tree planting, wider sidewalks, and so forth.

There are two main ways in which traffic flows can be reduced. The first is the physical removal of road space. Clearly, this cannot be done as a one-off, because this would be very disruptive. Using small incremental capacity reductions over a number of years, though, allows traffic to adjust to the new conditions easily and smoothly.

The second method does not involve removing road space but removing (short) through routes, requiring through traffic to use more circuitous routes. This was first tried in London in the 1960s (Pimlico Experiment), and researchers found no significant increase in traffic in surrounding roads

from displaced traffic. This is the inverse of the traffic law, which states that volume increases to fill the available space.

Environmental Capacity and Social Acceptance

Some roads have been built specifically to carry motor traffic, such as freeways, and others have evolved into arterial traffic streets, where previous residents have moved away and been replaced by commercial or retail uses. Streets where people live are not suitable for through motor traffic and have a maximum environmental capacity, variously thought to be no more than 200 pcu per hour, from residents' attitude and behavioral surveys.

Such residential roads, where they are also through routes, need to have traffic managed only to accommodate traffic that is accessing premises in the area. There are various methods to achieve this, ranging from road signs to reorganizing traffic movements to physically closing some roads to make through journeys impossible. This was pioneered in the Netherlands with *Woonerfen* ("home zones"). These traffic management measures not only calmed traffic, but traffic laws also gave priority to human-powered modes of travel—walking and cycling.

Motor cars and cities are almost the worst combination for the movement of people with a minimum impact on the environment. Cities where most travel is by car require a large proportion of the land to be given over to roads and parking. Motor traffic creates toxic air pollution, now the single most critical source of such pollution, known to kill many times more people than traffic crashes. Transit, walking, and cycling are more environmentally benign, but motorists with a choice appear to be unwilling to leave their cars at home. On top of this, traffic noise is now the single most intrusive noise nuisance in most cities, making conversations difficult in streets.

Improving Mixed Traffic Flow Safety

Slowing traffic reduces not only environmental impacts but also the consequences of collisions between soft slow-moving and hard fast-moving objects. Pedestrians hit by a car at 40 mph (65 km/h) stand less than 20 percent chance of surviving. At 30 mph (50 km/h), there is a 50 percent chance of surviving, and at 20 mph (30 km/h), there is an 80 percent chance of surviving.

Reducing vehicle speeds in principally residential areas, where most pedestrians are hit, will therefore significantly improve safety, without slowing journeys by very much. A 2-mile (3-km) journey at 20 mph (30 km/h) takes only six minutes, and at 30 mph (50 km/h), four minutes.

Traffic flows are more than the mechanistic movement of motor vehicles. They are fundamentally part of the transport system of a city and also reflect the environmental quality and civic expectations of its citizens.

Traffic Forecasts

Traffic forecasts are estimates of the number of vehicles or people taking a given route or using a given road (or other transportation project, from a specific bridge, to the 3:10 p.m. bus, to the Delta flight from Cleveland to Austin) in a given period of future time, and of the conditions of traffic as a result of that number and other available data. Such forecasts inform transportation planning decisions, and multiple forecasts can be used to choose between various options.

Traffic forecasts are a necessary part of the most basic parts of transportation planning; the decision whether to construct a commuter rail line from a city to a suburb depends on an accurate forecast of how

many residents of that suburb will use it to commute to the city, for instance, and the mapping of school bus routes depends on knowing how many students live along a given proposed route.

Traffic forecasts also impact decisions at higher levels of policy, such as the setting of speed limits, the deployment of highway patrol vehicles, building an expansion of an airport, or picking a location for a new school, park, or playground. They are also necessary components of other analyses, such as environmental impact statements, social impact statements, and the cost-benefit analyses of many transportation and infrastructure projects.

Traffic forecasts may also be prepared for a specific type of scenario rather than a specific period of time, such as forecasting the impact of a road closure, construction project, or weather event. Weather event traffic forecasts are important in developing weather emergency plans for a city or region, because the impact of flooding, fires, hurricanes, or ice and snow on traffic affects evacuation plans and the dispatch and deployment of emergency personnel, as well as other basic city functions.

The geographical area considered by a given traffic forecast or other transportation planning model is called a traffic analysis zone (TAZ). Zones may be of any size, but modern urban planning software usually assumes a zone with a population of less than 3,000. Census information provides population and socioeconomic data, and the specific types of data included in analyses vary from institution to institution, with each state's own Department of Transportation (DOT) typically providing a guidebook detailing which data to include. Usually, the number of automobiles and household income are both included, as they are valuable indicators of transportation usage and mode choice.

Four-Step Process

There are many methods of traffic forecasting and modeling, varying in methodology, sophistication, and appropriateness for different purposes. The classic urban transportation planning system model uses four steps: trip generation, trip distribution, mode choice, and route assignment.

Trip generation is the process of predicting the number of trips transpiring within the TAZ, whether originating or ending there. Depending on the purposes of the forecast, this may be expressed in terms of a number of trips within the period

of time being forecast or in terms of frequency of trips. There are various methods of trip generation. For intercity travel within the United States, the Transportation Systems Analysis Model (TSAM) is the nationwide standard.

Trip distribution is sometimes called destination choice, and it forecasts the end point of each trip. Specifically, it creates a trip matrix, listing the number of trips made within the traffic analysis zone between any two points. The importance of specificity of forecast in trip distribution varies according to the scope and purpose of a traffic forecast. For instance, it is all but irrelevant in the traffic forecast of the level of usage of a particular bridge. The trip distribution may tell you something about the effects of a detour should the bridge be made unavailable, but if the purpose is simply to determine the amount of wear and tear undergone by the bridge and how soon it will need maintenance, then trip distribution has little effect.

Replace the bridge with a highway in this example, though, and trip distribution differentiates cars that travel the highway's entire length from cars that travel for only two exits, which is important information for maintenance, toll revenue, safety and security, and predicting traffic problems. And if the highway were instead a subway system, trip distribution would be critical in understanding the subway's ridership, revenue, and whether passengers will be left behind at certain stops because of overcrowding.

Work on trip distribution models had been fairly primitive until Alan Voorhees's 1956 *General Theory of Traffic Movement*, which introduced a mathematical formula using land use to forecast traffic patterns. Voorhees's work continues to be fundamental in urban planning and the planning of public works, and it was his work that introduced the trip matrix. Subsequent work analyzed various models for accuracy by feeding them data to forecast situations where the results were already known, such as the amount of traffic in a given city in the 1940s.

Key to trip distribution models at the time was the gravity model, which posits a relationship between the increasing distance between two locations (where distance can also represent transit time or cost of transit) and a decreasing interest in passengers traveling between those two locations. The farther from the city you go, the fewer people are commuting home from it, for instance. The

exact rate of decline is dependent on context, but mathematical work in numerous areas continues to confirm the accuracy and usefulness of the gravity model's basic underlying relationship. Later work on trip distribution in the 1980s included methods that performed the trip-distribution and mode-choice stages in combination, and the borrowing of mathematical methods from other fields, such as entropy analysis from statistical mechanics.

Early trip distribution models were unable to model the effect of travel congestion on trip distribution, that is, the possibility that the presence of heavy traffic would alter a traveler's choices, which is clearly an important real-world phenomenon. This effect is sometimes called "travel resistance," while other models simply count it as travel time and are built such that increases to travel time in a given trip segment alter the trip matrix outcome.

One way to think of the effect of travel resistance is to consider a jogger who jogs for a half hour every

morning. Factors such as obstacles that impede his jogging and his own speed will determine the exact trip he makes, based on that half hour. When he first begins his jogging habit, this may be a short half-mile trip, while a year later it may be a two-mile trip, as his endurance has increased. This is a simplified model, because it assumes the existence of a rigid travel time budget that drives choices without the influence of other inputs, whereas real-world situations are more complex.

Mode choice is a hypothetical passenger's choice of transportation mode. Planning a subway system, for instance, requires making assumptions about how many passengers (and, broadly speaking, which passengers along which routes) will choose to use the subway and which will continue to use other modes of transportation, and what factors influence those choices or could cause them to change. (Those who choose pedestrian transportation but have access to subway transportation may

A train at Cleveland Circle on the Green Line "C" Branch of the Massachusetts Bay Transportation Authority subway in Boston, Massachusetts, serves as an excellent example of a mode choice model. Passenger behavior and the choices they make regarding their mode of transportation are important elements of traffic forecasting. A forecast can estimate the number of vehicles on a bridge, the ridership on a railway line or subway, the number of people at an airport, or the number of ships docking at a seaport.

elect subway transportation for weather-related reasons, for instance.)

Increases in automobile ownership can generally be assumed to decrease activity in several modes while increasing activity in driving. This is an area where the study of historical data is especially useful. Forecasting the effect of adding a new subway line can be informed by studying the effect of an earlier subway line, or a subway line in a significantly similar neighborhood in another city.

Mode choice models draw heavily on psychology, because passenger behavior must be modeled based on what passengers perceive rather than on what is true. They also frequently must use nested models. The potential passengers of our aforementioned new subway system are not choosing simply between car and subway, but between car and subway and walking and bicycle and taxi, and within those choices may have other choices to make.

In Boston, for instance, while using the Massachusetts Bay Transportation Authority (MBTA), there are two simple ways to travel from Cleveland Circle to Harvard Square, either taking the 86 bus, which runs infrequently but does not require any transfers and is cheaper than the subway, or taking the Green Line subway most of the way and then transferring to the Red Line. The subway runs more frequently, so, at any given point, the wait time before the trip begins is likely to be shorter if the subway is chosen, but the total amount of time spent in transit once the trip begins is longer and slightly more expensive. Bad weather may make the subway choice more likely, but an important factor is the perceived inconvenience of the need to transfer versus the perceived inconvenience of the longer wait at the bus stop. Another factor impacting choice is that each mode drops the passengers off at a different part of Harvard Square, which may be more or less near their final destination.

Route assignment is the last step of the four-step forecasting model, and consists of the creation of modeled traffic along specific routes. Having determined how many trips will be taken and how those trips will be distributed on the trip matrix, the forecaster then determines which mode of transportation will be used for the trips. The route assignment is the assembly of all this information.

Route assignment is affected both by travel demand—the number of passengers who need to go places—and network supply, which are the

available routes to take them to those places. Demand increases supply. Before a subway route from the city to the suburbs is created, traffic between those points may consist mainly of commuters and special-event attendees (for example, sports fans, concertgoers, convention attendees), but the creation of the route will increase the total amount of traffic from the suburbs to the city, not simply divert the existing bus and car traffic onto a different mode.

Traffic Impact Assessments

Traffic impact assessments (TIA), also called traffic impact reports, traffic impact analyses, and traffic impact studies, present information on the projected effects on traffic of a planned development, such as a new office building, stadium, shopping center, or residential development, and can also be used to evaluate the effects of a possible transportation project. They are principally quantitative rather than qualitative analyses, and often rely on standardized methodologies and data sources. Since the late 1980s, state agencies have increasingly required traffic impact assessments as part of the development review process, and they have

been part of the process for municipal agencies for much longer than that. TIAs are usually prepared according to specific guidelines required by the relevant state or municipal agency, but may contain information exceeding those required minimums. A number of software packages exist to assist with the traffic impact analysis process.

TIAs may be used by city planners in considering the merits of a proposed transportation project, anticipating effects that may need to be addressed, and comparing the effects of multiple possible solutions to a transportation problem. The scope of the project being examined may be as simple as a new turn lane or as complicated as a new highway or the street layout of a planned community. A traffic impact assessment may also be one component of a larger impact assessment that considers the economic and environmental impacts of a proposed project as well.

New transportation infrastructure and new development always generates new traffic. Depending on the capacity of the transportation infrastructure used by that traffic, this may result in numerous negative effects, including traffic jams, accidents, the environmental effects of air pollution, the social effects of noise pollution, and increased fuel use and travel time. Further, driver behavior may change in ways unintended by the planners. For instance, if new development results in traffic congestion near that development, drivers ordinarily using those roadways as throughways may divert to alternate routes, which may “squeeze” the congestion elsewhere or may direct high-speed traffic to lower-speed-limit roadways. Commuter traffic may wind up rerouting through largely residential neighborhoods unaccustomed to it.

Similarly, new transportation infrastructure will impact not only the traffic patterns of the traffic using the infrastructure itself but the routes drivers use to reach the new infrastructure. A new highway on-ramp may “pull” traffic accustomed to using an on-ramp farther upstream, creating new traffic patterns in the form of the routes they use to reach the new on-ramp, while bleeding that traffic off the routes they had used to reach the existing one. In some cases, of course, this may in fact be the goal: the new on-ramp may be constructed specifically in order to alleviate congestion in an area where population density has risen. In other cases it may be an unforeseen side effect of an

on-ramp built to provide access to a new commercial development.

Traffic impact assessments vary in their complexity and depth in accordance with the project being examined. They are an important part of land use and urban planning. There are standard statistical analysis tools used to predict, based on the available information about existing traffic patterns and traffic patterns in situations similar to the one proposed, information like additional traffic volume, wear and tear on infrastructure and the necessity and cost of future repairs and maintenance, and increases to the likelihood of traffic collisions in problem areas.

Trip Generation Data

One of the basic components of constructing a traffic impact assessment is assembling trip generation data. Trip generation is the number of vehicle trips that are expected to be generated as a result of the project during a specified hypothetical period of time. Sometimes trip generation data will be determined both for an average day and for peak hours, since the latter is crucial information in examining the possibility and effects of congestion. The Institution of Transportation Engineers (ITE) provides a trip generation manual that is the standard source of trip generation data in the United States. For instance, according to the ITE’s manual, each dwelling unit in an apartment building generates 0.41 peak hour trips, while each dwelling unit in a retirement community generates 0.29 peak hour trips, and each employee in an office building generates 0.48 peak hour trips.

When trip generation rates are constructed, they make certain assumptions about pass-by rates, among other factors. A pass-by trip is one in which traffic travels to a particular destination en route to some other destination. These trips are therefore not generated, as such, by the proposed project, because they would have occurred anyway. For instance, convenience stores and fast food restaurants with drive-through windows are assigned high pass-by rates by the ITE (40 percent in both cases) because most drivers arriving at these locations are stopping off (or driving through) as part of some other trip that they would be taking anyway. On the other hand, fine-dining restaurants have a low pass-by rate because most drivers arriving there have taken a trip for the express purpose of dining there and would not have made the trip otherwise.

Obviously, high pass-by rates reduce trip generation numbers. This becomes further complicated when considering trip generation for multiuse developments, which overall reduce trip generation.

In some cases, trip generation may be the only part of a traffic impact assessment that is required, insofar as other elements are required only of projects that will result in more than 100 peak hour trips (the threshold recommended by ITE). In other cases, a traffic impact assessment will be needed regardless of trip generation data, because of other factors. Common factors that result in a traffic impact assessment being required regardless of trip generation include the use of a drive-through window in a proposed commercial development, developments with inadequate sight distance, proposed access roads without left turn lanes, and developments on high traffic roadways.

Elements

A traffic impact assessment typically covers certain basic areas. It begins with a description of the proposed project the impact of which is being assessed and of the traffic area under study. In the case of a development or a new element of infrastructure, this includes specifying the locations of access points, such as the connecting streets to a new road, or the road on which a new development would be located. The peak hours used in the study are identified explicitly in order to make the terms of discussed impacts clear.

In order for the traffic impact assessment to be put in context, a discussion needs to follow of the existing traffic conditions, including not only the relevant transit infrastructure but traffic patterns, intersections, presence or absence of traffic signals, and traffic counts both during peak hours and as daily averages. In general and as applicable, any time a projected traffic statistic is going to be discussed in the assessment, the current and historical analogues to that statistic should be presented for purposes of comparison. For instance, if a new shopping center on a certain road is going to generate a certain number of trips, it needs to be clear how significant that number is based on the traffic the road already experiences.

After thus discussing present traffic conditions, projected trip generation is discussed, with explicit reference to the data and methods used to project it. Tables should show estimated traffic movements,

including direction and volume. In the case of a development, matters like parking and (in applicable climates) snow plowing must also be addressed. Depending on the project being examined, it may also make sense to discuss pedestrian and bicycle traffic, or the projected access and use by trucks.

Finally, recommendations may be made. The assessment may have made it obvious that if the project is built, there will be a need for other infrastructure in support of it, such as additional roads or turn lanes, traffic signals, ramps, or parking accommodations. Projections may show that traffic will need to be rerouted in order to avoid conflicts with zoning laws in the impacted area, or proposed access or egress points may need to be relocated. Any potential traffic concerns should be highlighted.

Software

There is a wide variety of software that can be used in the traffic impact assessment process. Traffic and travel speed can be modeled with appropriate simulation software, while the Environmental Protection Agency provides a model, CAL3QHC, for modeling carbon monoxide concentrations resulting from traffic flow. 3D visualizations can integrate information into an animated simulation of the driving experience, and geographic information systems can be used to present the modeled results in a geographic context.

Example of a Traffic Impact Assessment

The exact requirements of a traffic impact assessment vary by the requiring agency. For instance, in the small city of Nashua, New Hampshire, developers are required to submit a Traffic Impact Report that follows ITE guidelines and relies on ITE methodologies (such as for trip generation as discussed above). Every Traffic Impact Report filed with the City of Nashua Board of Public Works must cover these required areas, with the principal purpose of analyzing the capacity of the roadways impacted by the proposed development: safety, circulation patterns, traffic control needs (such as traffic lights, signage, or turn lanes), transit needs or impacts, neighborhood impacts, parking issues, effects on pedestrian and bicycle traffic, service and delivery vehicle access, driveway location and operation, air quality and noise impact, signalized and unsignalized intersections adjacent to the site, and all site access points.

The Nashua Board of Public Works specifies exactly which baseline conditions, at a minimum, must be included in the report for purposes of comparison: peak period turning movement counts collected on a midweek day (Tuesday, Wednesday, or Thursday) from 7 A.M. to 9 A.M. and 3 P.M. to 7 P.M., weekend counts in the case of retail areas that already experience high weekend traffic volume, and in some cases origin-destination studies. Counts should be specific about vehicle type, separating counts for passenger cars and motorcycles (together), single-axle trucks, multi-axle trucks, buses, and school buses. Maps should be provided to show current traffic flow, while analyses demonstrate the roadway's current capacity and level of service. Key locations in the study area (such as intersections and access points, traditionally) should have their accident history reviewed.

Traffic Impact Reports must be delivered to the Nashua Traffic Engineer at least three weeks in advance of a scheduled meeting before the board to discuss its contents. The board defines specific conditions in which Traffic Impact Reports are required: any development that generates 75 trips per hour between commuting peak times (7–9 A.M. and 4–7 P.M.), any development generating 100 trips per hour during any 24 hour period, any development generating 1,200 total trips in any 24 hour period, any permanent roadway closure, any temporary road closure over 14 days in length, and any other development at the discretion of the Nashua Traffic Engineer.

To take one example from Nashua, on Broad Street, an old state highway connecting neighboring towns to the interstate, a local business owner purchased a former barn that had been converted into an antique store before that store folded. The purchase was made with the intent of extensively remodeling the barn and reopening it as a convenience store aimed at both commuters and residents of the neighborhood, which had not had a local convenience store since a fire claimed the previous one some years earlier. Because the store was to open in a neighborhood that was almost entirely residential, consisting of both condominium developments and single-family homes (the only major exceptions being a church and a motel), special attention was paid to the traffic impact.

Trip generation was believed to be fairly low, since the whole business model depended on attracting pass-by traffic, but despite being below the threshold,

a traffic impact report was required because of concerns over increases in pedestrian traffic and the amount of customer traffic and delivery vehicles that would be turning in and out of the store's small parking lot. Eventually, the Board of Public Works and Zoning Board approved the addition of a pedestrian crosswalk with a traffic light that would stop traffic only when a pedestrian was crossing.

The store remained in business for only a short period due to the building owner's eventual insolvency, and after the building had been foreclosed upon by the bank and resold, another plan to repurpose it was brought before the Board of Public Works: to turn it into a Hindu temple for Nashua's growing South Asian population. Here again traffic was the main concern.

The predominantly, if not entirely, non-Hindu Board needed to have it clarified for them that the traffic patterns for a Hindu Temple would not be analogous to those of the neighborhood's Christian church, in that most drivers would be arriving for individual prayer rather than for weekly community services. Traffic would thus be distributed throughout the week rather than the extremely unequal distribution experienced by churches where the focus is nearly entirely on a weekly Sunday service.

The developers argued that for this reason, given the traffic light and pedestrian crosswalk already in place, the parking lot was sufficient for the temple's needs and would not result in cars parked on the street or interfering with the work of snow plows in the winter (a frequent concern on Broad Street, which needs to be plowed early and often because of the commuter traffic volume but has insufficient shoulders for much of its length for snow displacement). The board agreed and approved the plan.

Traffic Incident Management

Traffic incidents have become a major cause of congestion and a significant threat to urban mobility. The Federal Highway Administration (FHWA) reported in 2005 that about 25 percent of congestion in the United States is incident related. The Texas Transportation Institute (TTI) estimated that traffic incidents accounted for about 52 percent to 58 percent of the total delays experienced by motorists in all urban areas. Similarly, the Conference of European Directors of Roads (CEDR) reported in 2011 that road incidents account for 10 percent to 25 percent of congestion across Europe. Implementing traffic incident management (TIM) programs has been proven to be an effective way to reduce the duration and impacts of traffic incidents, mitigate congestion, and improve safety.

FHWA defines TIM as

... a planned and coordinated multidisciplinary process to detect, respond to, and clear traffic incidents so that traffic flow may be restored as safely and quickly as possible.

Traffic incidents include any events that affect traffic flow on the roadway, such as disabled vehicles on the roadway or shoulder, vehicle fires, road

debris, emergency roadwork, police activities, and vehicle crashes. Consequently, a variety of public- and private-sector partners are involved in TIM, including law enforcement, fire and rescue, emergency medical services, traffic management agencies, towing and recovery, hazardous materials management, and others.

In the United States, law enforcement agencies such as state police and highway patrols, local police, and county sheriffs are usually the first responders to traffic incidents. Depending on the nature of the incidents, they will request and coordinate services of other partners. For example, fire and rescue teams may respond to fires and hazardous materials spills, while Emergency Medical Services will respond to the needs of primary medical care and transport of victims. Transportation agencies are usually responsible for developing and implementing traffic management plans to protect the incident scene, control traffic, and distribute traffic information to reduce delay and potential secondary accidents related to the incidents.

TIM in Europe also involves a range of government agencies that provide incident response services similar to their counterparts in the United States. Because European countries are usually geographically more compact and more densely populated, European practice in TIM has a more integrated approach. Many European countries have set up a national framework for incident response, and responders from different government agencies usually receive collaborative training programs.

State of the Practice

In early TIM practice, the responsibilities of incident response were distributed to different agencies, and there was no institutionalized framework to integrate efforts of different incident response agencies. Over time, practice has proven that good coordination and collaboration between different agencies play a key role in improving the efficiency and effectiveness of incident response.

In the United States, the 2005 Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) requires the development and implementation of a Strategic Highway Safety Plan (SHSP) by each state; it also clearly articulates the needs and provides guidance for developing a formalized TIM program. This TIM program

provides clear top-down authorization for resource sharing and joint operations, establishes a chain of command and ensures accountability, guides on-scene operations, and sets up training programs.

TIM programs help improve coordination between traditional incident responders. Over the years, they have also started to foster the formation of multiagency task forces to further integrate efforts of different agencies. For example, the Maryland Department of Transportation, Maryland Transportation Authority, and Maryland State Police, in cooperation with other federal, state, and local agencies, set up the Coordinated Highways Action Responses Team (CHART) as a joint effort to improve real-time operations of Maryland's highway system through teamwork and technology.

CHART operates a variety of traffic incident response units to provide efficient incident response and to restore highway capacity as soon as possible. For example, emergency traffic patrols help detect and locate traffic incidents quickly. Emergency response units then set up overall traffic control at accident locations. Freeway Incident Traffic Management (FITM) trailers, pre-stocked with traffic control tools such as detour signs, cones, and trailblazers quickly set up preplanned detour routes according to the needs.

Regional Traffic Operations Centers (TOCs) and the Statewide Operations Center share incident information with other related agencies and distribute the information to the public through various traveler information systems. A study in 2009 showed that CHART has been able to reduce the duration of incidents by about 25 percent for the last seven years, yielding significant benefits to both motorists and the entire travel environment. Similar efforts can also be seen in other states.

Deployment of advanced technologies has also become an important aspect of new TIM strategies. For example, more closed-circuit television cameras (CCTV) have been deployed along major corridors to enhance automatic and early incident detection and verification. Enhanced 911/automated positioning systems have been used to capture emergency caller's location with higher accuracy. TIM programs work closely with traffic management agencies to distribute incident and traveler information through channels such as variable message signs (VMS), traveler information Web sites, and conventional media. Timely distribution of incident information is crucial

for mitigating congestion related to traffic incidents. New on-scene emergency lighting systems and high-visibility safety markings have been used to enhance the safety of responders and reduce the probability of secondary incidents.

Similarly, recent development of TIM practice in Europe highlights the importance of coordination between different agencies, cross-border cooperation, and application of new technology. For example, EasyWay is a project for harmonized Europe-wide intelligent transport systems (ITS) deployment on main Trans-Europe Road Network (TERN) corridors supported by the European Commission. One of its services is to share information on incident management capacities on the TERN among partner agencies such as the police, road operators, and traffic management authorities. Its long-term objectives include distribution of incident and traffic information among travelers.

TIM Evaluation

Design and implementation of advanced TIM requires significant investment. There is a strong need to evaluate the performance of TIM and present its benefits to stakeholders. It is challenging to estimate the benefits of TIM projects because capturing the impacts of traffic incidents with limited field data is by itself a big challenge. For example, the Texas Transportation Institute's "2011 TTI Urban Mobility Report" managed to directly measure delay using data collected by vehicles equipped with Global Positioning System (GPS) probes but could not assign the delay to any specific causes. Researchers have to use a variety of tools to estimate the impacts of traffic incidents.

Examples range from the simplest static queuing model to more advanced empirical models such as procedures recommended by the *Highway Capacity Manual* and site-specific mesoscopic and microscopic traffic simulation models. Traffic simulation models, if correctly calibrated, allow researchers to collect a variety of system performance data for scenarios both with and without the TIM system implemented to make a meaningful comparison. However, it requires a lot of resources to develop and calibrate a traffic simulation model for a corridor.

Further, it is not practical to use simulation tools to evaluate the performance of TIM on a regional network. Instead, researchers usually use incident duration as a surrogate to evaluate the

performance of TIM systems. The *Highway Capacity Manual* defined the incident duration to be the time elapsed from the onset of an incident to the end of its clearance.

An effective TIM could help with earlier incident detection, more efficient response team dispatching, better on-scene coordination, and shorter clearance time. Shorter incident duration usually implies great time savings for travelers, especially on busy freeways. Therefore, comprehensive and systematic incident data collection plays a key role in TIM evaluation. For example, the CHART program in Maryland has developed a model to capture the benefits (travel time savings, reduction in fuel consumption, and fewer emissions) associated with TIM implementation and continuously monitor the system performance over years using the incident database it builds.

Service Patrols

Service patrols have been proven to be an effective tool for TIM. The patrol team can help detect and verify the incident, protect the scene, set up traffic control, request additional resources if necessary, and support quick clearance of minor incidents. Many U.S. states have set up patrol services. Examples include the Freeway Service Patrol (FSP) programs in California and Florida, the Freeway Incident Response Safety Team (FIRST) in Minnesota, and the Highway Emergency Response Operators (HERO) in Atlanta, Georgia. Significant benefits associated with patrol services have been reported in a variety of studies. For example, overall incident duration has reportedly been reduced by 28.6 percent in Maryland and 12 percent to 36 percent in Salt Lake City, Utah, as a result of service patrols. In literature, benefits are reported to consistently outweigh cost. Some TIM agencies also deploy equipment and responders at key locations near areas that suffer from high incident rates. This strategy of prepositioning resources could complement the service patrols to further improve incident response efficiency. For example, the Tennessee Department of Transportation has deployed Ready Response Trailers stocked with traffic control devices at 15 strategic locations since 2002.

Research on TIM

Significant research efforts have been dedicated to further improving efficiency of TIM strategies.

For example, researchers are developing active corridor management (ACM) strategies to mitigate non-recurrent congestion associated with traffic incidents through proactive measures. ACM strategies require quick detection and evaluation of traffic incidents, and deploy strategies such as dynamic routing guidance, adaptive signal control, variable speed limit, and temporary shoulder use.

Accurate estimate of incident duration plays a key role for the development and implementation of ACM strategies. Many models, ranging from simple linear regression to complicated Bayesian network, have been developed in literature, and researchers are continuously improving their accuracy with new data and modeling tools.

Another widely studied but still challenging research topic is finding the optimal way to divide highway networks into different patrol zones, and the optimal patrol route within each zone to provide the most effective highway patrol services with limited resources. Early researchers solved this problem using a variety of tools, including the classic median models, the maximal coverage location problem (MCLP), the hypercube queuing model (HQM), among others. However, the recent development of highway patrol services requires a dynamic program operated in real time with great flexibility (for example, capability to reallocate resources if some units have been dispatched elsewhere). More efforts in both theoretical and empirical research are needed to address these challenges.

Traffic Information and Control Systems

Traffic information and control systems monitor the movement of people, goods, and vehicles to ensure their delivery is as efficient and seamless as possible throughout the transportation system network. There are unique control systems for all modes of transportation, including roadways, airports and airways, railways, coastal and inland waterways, and pipelines. The goal is to increase safety, convenience, and capacity of the transportation network.

Traffic Control Systems

The traffic signal, even if it is a simple road sign at an intersection, impacts virtually everyone every day. Individual traffic signals, if implemented and followed out properly, achieve networkwide traffic operations objectives, which consist of intersection traffic signals, a communications network to tie them together, and a central computer or network of computers to manage the system. Techniques to monitor such systems include time-base and hardwired interconnection methods. Coordinating these methods across agencies requires data sharing and agreement upon traffic signal controls.

Roadway traffic control systems are intended to improve safety, increase the operational efficiency and capacity of the roadway, and contribute

to the traveler's overall comfort and convenience. The areas monitored begin small at isolated intersections using signs and markings, and expand to sophisticated traffic control centers, which have the ability to react to changes in the traffic environment. Traffic control systems are used at roadway intersections, on highways and freeways, at ramp entrances to freeways, and in monitoring and controlling wider-area transportation networks.

People accept and even demand traffic signals to ensure safety and mobility. Drivers usually assume that the responsible agency can efficiently operate signals, such as traffic lights, so motorists usually report only the most obvious failures. Inefficiencies can cause longer trip times and higher fuel costs.

Research and applications demonstrate the effectiveness of signal system improvements in reducing delays, stops, fuel consumption, emission of pollutants, and accidents. Certain traffic systems have been termed adaptive, as in they have the ability to alter signal timing in response to both short-term and longer-term variations in traffic. These systems not only provide more effective control of traffic but also require fewer human and financial resources to update the system's database.

Road traffic controls are monitored by the Federal Highway Administration (FHWA), although state and local agencies have their own variations of standards set forth by the *Manual on Uniform Traffic Control Devices* (MUTCD). Traffic controls vary extensively throughout the United States, depending on the type of roadway being traveled and the kind of vehicles passing through. For this reason, consistency in traffic control certification is not found throughout the nation. For instance, the FHWA does not address certification methods for traffic controllers, flaggers, and other traffic personnel because this is deemed a state or local responsibility. Safety is measured by the Occupational Safety and Health Administration (OSHA) and state safety departments.

Other Modes of Transportation

The U.S. federal government has designated airspace as uncontrolled or controlled. In uncontrolled airspace, pilots may conduct flights without specific authorization, such as private pilots or those using recreational aircraft. In controlled airspace, pilots may be required to be in communication with an air traffic control facility to receive instructions on when they may pass, land, or take off.

Air traffic control is but one of many control systems throughout the transportation system network. Air traffic controllers, who work in towers like this one in Billings, Montana, direct aircraft in order to prevent collisions, provide information to pilots, and expedite the flow of air traffic.

Railroad operations serve both freight and passengers. Traffic controls are especially important as these trains, both freight and passenger, travel on the same tracks and almost exclusively rely upon traffic controls to determine the right of way.

Railroads use both semaphore and light signals for traffic control. Semaphores convey visual messages to train operators based on how the train should be managed and operated. Block signaling prevents collisions with preceding or oncoming trains. Track sections are divided into blocks and one train is permitted to occupy one block at any time. Automatic circuitry monitors which vehicle is occupying each block, and the region it monitors could exceed hundreds of miles. These monitors

look for present and oncoming trains to monitor stops and speed. Dispatchers at circuitry boards can monitor these action by watching colored lights on the board and other visual displays.

To control a boat or vessel, occupants rely less upon traffic control devices and more on the use of informational tools, which can tell them longitude and latitude coordinates, the traveling of larger vessels nearby, and weather conditions. Visually, buoys indicate areas that boats can navigate by whether they are lit or not. Lighthouses also provide a landmark for boats to know where land is and to shine a light on the waters. Lighthouses have fog signals and radio beacons, which aid boaters during periods of limited visibility resulting from inclement weather conditions.

Pipelines that carry various materials are also included in the U.S. transportation network. Oil, oil by-products, natural gas, and fertilizers are the most popular goods transported through this network. Valves, pumps, and compressors are the means by which these substances are navigated throughout the pipeline system.

Travel Demand Management

A highly developed system of streets, highways, freeways, and various forms of public transportation serves the cities in the United States. Population and urbanization growth have led to a growing travel demand. The ability to meet this demand and provide new or improved transportation, however, has been difficult.

The wide spectrum of travel demand management actions includes promotion of nonauto modes of travel, special treatment for high-occupancy vehicles (HOV) within designated lanes, preferential parking for HOV, incentives to reduce peak-period travel, telecommuting, nonstandard workweeks (for example, four 10-hour days), and transit service improvements.

Many travel demand management measures impact or depend on the efficient and effective use of traffic signal systems, freeway traffic management systems, and traveler information systems. Efforts to promote transit usage become less effective if, for example, buses meet unnecessary delay from inefficiently operated signals. Vanpool and transit usage become more attractive if these vehicles can travel on less congested HOV freeway lanes. Therefore, urban highway control systems and information

systems prove critical to the overall operational effectiveness of transportation facilities.

In the past three decades, the transportation network in the United States has experienced tremendous growth of advanced traffic control and management systems for both freeways and streets. Computers now control streets and highways, and their functionality has been accelerated by the revolutionary advances and associated cost reductions in communications and electronic technologies.

Traffic Laws and Enforcement

Traffic laws may be considered a form of civil engineering. Almost solely a product of the 20th century when the United States became an automobile society, traffic laws are codified by states, counties, and municipalities in order to ensure the orderly

movement of traffic and to minimize hazards to safe travel. Enforcement of traffic laws relies upon policing. Forty-nine states in the United States have special police forces, variously designated as highway patrol, state patrol, or state police, who devote a substantial part of their time to traffic duties. Major metropolitan police agencies typically have a traffic division, and local police officers in smaller communities typically spend time not required for other activities in traffic patrol.

Law enforcement officers issue tickets to drivers or other road users who violate traffic laws. Traffic tickets generally are divided into two categories: moving violations (with speeding being the most common) and nonmoving violations (with parking violations being the most common). Although definitions vary from state to state, most traffic tickets are considered infractions. More serious offenses are labeled violations and may be considered misdemeanors or felonies, with the appropriate penalties.

The Need for Traffic Laws

Traffic laws did not originate with the advent of the automobile. Julius Caesar banned wheeled traffic from the streets of Rome during most daylight hours in an effort to relieve congestion. The traffic fatality rate in urban centers in the late 19th century when horse-drawn vehicles clogged city streets far exceeded 21st-century fatality rates in the same areas. It was the accidents caused by these vehicles, not automobiles, that prompted William Phelps Eno, "the father of traffic safety," to invent the "rules of the road" and write a city traffic code for New York City in 1903, the first such code. Eno is credited with devising the stop sign, the stop light, the yield sign, the crosswalk, the pedestrian island, the one-way street, the traffic circle, and the taxi stand.

Soon after Eno developed his plan for New York City, the automobile brought new concerns, and it became clear that regulations for these new vehicles were needed. California made driving an unregistered vehicle and driving without a license a misdemeanor as early as 1905. In the last quarter of 1906, the New York City police arrested 646 people for violations of laws and ordinances related to motor vehicles. States saw the need to require the registration of vehicles well before they became concerned with issuing drivers a license. In 1901, New York became the first state to register automobiles;

by 1918 all states required license plates. By the 1920s, cities, plagued with congestion, accidents, and parking problems, were imposing speed limits, installing traffic signals, designating one-way streets, and restricting parking.

By the end of the 1920s, three-fourths of American households owned a car, but laws governing those who could drive automobiles were inconsistent at best and nonexistent in many cases. In 1903, Massachusetts and Missouri became the first states to issue a driver's license, but no examination was required. As late as 1935, only 39 states required licenses for drivers, and examinations were still the exception among the states that did require a license. Rhode Island became the first state to test individuals on their driving skills before issuing licenses in 1908; New Jersey followed in 1913. The *New York Times*, which had reported concern about accidents due to driver carelessness and inexperience in 1907, expressed the hope that other states would follow, but it was 1924 before New York required either a license or an examination of a driver. As late as 1950, six states still did not require an examination. The last state to require drivers to pass a driving exam was South Dakota in 1959.

Licensing and registration were just a small part of an increasingly complicated issue. The sheer volume of court cases involving violations of traffic laws was creating a burden for the nation's cities. In 1942, an estimated one in eight drivers in the United States went to traffic court, and traffic violations were involved in at least half of all accidents. Automobile accidents were responsible for 30,000 deaths and 1,250,000 serious injuries each year.

Although conviction rates were high, averaging about 80 percent, penalties were low or not imposed at all. Drivers' records were rarely examined, so repeat offenders were not identified. States and cities were faced with rising costs for implementing and enforcing traffic laws required by the transition to the automobile as a primary mode of transportation. The lack of uniformity among the states added to the chaos.

The Uniform Vehicle Code

In 1924, U.S. Secretary of Commerce Herbert Hoover called for the first National Conference on Street and Highway Safety. Representatives from 43 states and various organizations with connections to

traffic safety—nearly 1,000 delegates in all—attended the conference. Many of the reports submitted to this conference noted the absence of uniform traffic laws. In direct response to this concern, Secretary Hoover appointed a Committee on the Unity of Laws and Regulations under the auspices of the National Conference on Street and Highway Safety in April 1925. This committee reviewed, revised, and approved a draft of the codes by the 1923 committee. The full conference repeated the review process, and on August 20, 1926, the first edition of the Uniform Vehicle Code was published. A model for the traffic ordinances of municipalities, based on ordinances of 100 cities, followed in 1928.

The National Committee on Uniform Traffic Laws and Ordinances was created in 1947 and has continued the process of reviewing and revising the code and the ordinance to accommodate changing times. Although states are not bound by the Uniform Vehicle Code, most states have adopted the laws, in whole or in part, as the basis for the laws and regulations related to traffic.

In its early stages, the move toward uniformity of traffic laws was seen as the province of individual states, and the choice to adopt the uniform code was cooperative action. While some laws recommended as best practices in the Uniform Vehicle Code gradually gained widespread adoption, the pace was slow. For example, Indiana passed the first state law defining driving under the influence in terms of blood alcohol concentration (BAC) in 1939, and the Uniform Vehicle Code adopted that law in 1944. But more than a dozen years later, only 30 states had adopted the BAC definition. The 1960s altered the balance between the states and the federal government. The Highway Safety Act and the National Traffic and Motor Vehicle Safety Act, enacted in 1966 in response to soaring numbers of traffic fatalities and the number of cars on American roads, gave the federal government the power to establish safety standards and to require each state to ensure that its rules of the road were uniform within all its jurisdictions and consistent with plans of other states.

Since the enactment of those laws, the federal government has tied the allocation of highway funds to the passage of laws governing implied consent, which says driving a vehicle implies consent to a chemical test to determine BAC level and motorcycle helmet use. The history of the latter

affirms the effect of federal pressure. In 1967, the federal government required that states enact helmet laws in order to qualify for certain federal safety programs and highway construction aid. By the early 1970s, almost all states had comprehensive motorcycle helmet laws, but when Congress ended the Transportation Department's authority to assess financial penalties on states without helmet laws in 1976, state legislatures began repealing the laws.

The Enforcement of Traffic Laws

Traffic enforcement is the most recognizable and universal police function. According to a 1999 Department of Justice estimate, more than half of the contacts between police and citizens nationwide occurred at traffic stops. Speeding is the most common reason for ticketing a driver. On an average day, 112,000 drivers in the United States receive tickets for exceeding the posted speed limit at an average cost of \$152. The total annual cost of speeding tickets is more than \$6 billion. In 2010, over 1.4 million drivers were arrested for driving under the influence of alcohol or narcotics. Most of these tickets were issued by highway patrol officers. In New York State, for example, state troopers comprise less than 6 percent of the state's total law enforcement personnel but issue 55 percent of all speeding tickets.

Doubtless, the fact that about one-fourth of U.S. citizens have received a traffic ticket for a moving violation (speeding, running a red light, passing illegally, etc.) contributes to the American tendency to view traffic violations as "folk crimes" as opposed to "real crimes." Some even argue that ticketing violators does little to deter them, a claim supported by several studies from the 1970s and 1980s that concluded that the level of police enforcement showed no correlation to the vehicle accident rate. More recent studies offer a different view. A 10-year Canadian study published in 2003 concluded that at least in countries with heavy motor vehicle traffic, enforcement of traffic laws reduced the number of traffic fatalities. An investigation of the effect of a 33 percent reduction in the number of full-time roadway troopers in Oregon found that at the same time the national fatality rate was falling, traffic fatalities in Oregon increased by 19 percent, incapacitating injuries by 14 percent, and visible injuries by 12 percent

compared to the three-year period before the layoffs. Studies in three other states reported comparable results. Researchers concluded that enforcement can play a significant role in driver behavior.

The Department of Justice initiative Data Driven Approaches to Crime and Traffic Safety (DDACTS) introduced in 2008 uses traffic law enforcement to address both traffic violations and crime by putting "high-visibility enforcement" in geographic areas that have been identified as having heavier than average concentrations of either. The program uses data collection and analysis to deploy limited resources in the places where that will make the greatest difference. Cities like Baltimore, Maryland, that have used the DDACTS model have seen reductions in traffic crashes and crime.

Technology is changing the process of traffic enforcement in the 21st century. Perhaps photo enforcement is the most controversial of automated enforcement devices. Substantial evidence supports the claim that traffic cameras discourage violators and decrease accidents. An Insurance Institute for Highway Safety study reported a significant decline in red-light running at intersections with cameras and also nearby intersections without cameras as much as a year after the cameras were first used.

As of 2013, traffic cameras were in use in 582 communities nationwide to catch violators who speed, run red lights, or commit other violations. Critics charge that the use of cameras has more to do with increasing revenues than with public safety. A single camera on one busy road brought in more than \$11 million in just two years. Light detection and ranging (LiDAR) has proven superior to traditional radar in detecting speeders because it creates a high-resolution image that identifies vehicle make, model, license plate number, and facial characteristics of the driver. A distance between cars mode makes it possible to document tailgating, an offense notoriously difficult to prove. Electronic traffic citation software is replacing traditional paper tickets and reducing the roadside risk to ticketing officers at the same time.

Traffic Management Systems

Growing populations, urbanization, and globalization are all placing unprecedented stress on transportation networks worldwide. Those who face the challenge of a daily commute in one of the world's large cities know well the complexity and chaos placed on transportation networks.

The developers of traffic management systems (TMS), also known as advanced traffic management systems (ATMS), attempt to bring some order to that chaos. The term *traffic management systems* is a fairly broad term, which is used to describe any number of configurations of components that can be used to alter traffic flows within a metropolitan area. Traffic management systems are a type of intelligent transportation system (ITS); such systems may monitor any type of transportation system in efforts to optimize travel in metropolitan areas.

Elements included in a TMS may include communicating with commuters while they are in their vehicles, real-time traffic monitoring, and incident monitoring. Examples of especially successful traffic management systems can be found in the Minneapolis/St. Paul, Minnesota, metropolitan area and Atlanta, Georgia. Critics of TMS have claimed that their existence has not been scientifically justified,

and that these systems unduly support personal motor vehicles over other types of transportation.

What It Is, How It Works

In North America, an ITS is primarily concerned with automotive transport. Regardless of how individuals feel about America's dependence on automobiles, it is critical that these automotive transportation systems operate in as optimal a fashion as possible.

The operators of ITS in North America attempt to alter traffic flow by providing information to users in a way that will make automotive travel quicker and more efficient. There are six metrics that all intelligent transportation systems use: increasing transportation-system efficiency, enhancing commuter mobility, improving safety for commuters and bystanders, reducing automotive fuel consumption and the environmental cost of said consumption, increasing economic productivity, and creating an environment conducive to ITS markets.

Regardless of how independent people feel in their automobiles, it is possible for a driver to be manipulated. This manipulation is not conducted out of any desire to micromanage the daily routine of drivers. Instead, these efforts are conducted to optimize traffic flow in an area that may be larger than a major city.

When driving on roads controlled by a TMS, this outside manipulation likely comes from a central point that is governed on a top-down management model. The directors of this type of model seek to integrate technology to improve vehicle flow and commuter safety.

While each TMS is different, they all follow the same basic set of rules. All traffic management centers use real-time traffic data from some type of sensor to a central transportation management center (TMC). The sensors that could be used include real-time traffic monitoring sensors, incident monitoring sensors, traffic cameras, ramp meter monitors, and traffic signal monitors, and each of these types of sensors includes many models and variations.

Once the information from the sensors arrives at the TMC, it is processed and a number of actions may be taken by utilizing a variety of output devices. Dynamic message signs (DMS) are stationary traffic control devices that can provide one or more messages. They are capable of giving

either real-time advice, such as accident information, or basic driving reminders, such as “Don’t text and drive.”

Active traffic management (ATM) systems, also known as “managed lanes” or “smart lanes,” are those that change the permissible direction of lanes in efforts to allow for greater traffic flow where needed. Road weather information systems (RWIS) and other automated weather warning systems monitor weather and road conditions and provide commuters with important information regarding road safety. Highway advisory radio utilizes specially designated radio stations to broadcast important information to commuters. Through these systems, commuters can be informed of critical traffic data and take action accordingly.

Examples and Criticisms

Examples of highly functioning TMS systems can be found in Minneapolis and Atlanta. The IRIS (Intelligent Roadway Information System) system serves the Minneapolis-St. Paul metropolitan area. This open-source project is overseen by the Minnesota Department of Transportation and was put into place in 2007. The primary purpose of IRIS is to monitor and manage interstate highway traffic. IRIS assists Minneapolis’s commuters through the use of DMS signs, RWIS monitors, and traffic cameras.

The Georgia Navigator (also known as Georgia NaviGator) serves the Atlanta metropolitan area, where more than half of the state’s population lives. The Georgia Navigator was installed in April 1996 as part of the preparations for the 1996 Summer Olympics.

Georgia Navigator is overseen by the Georgia Department of Transportation. Hardware integrated into Georgia Navigator includes traffic cameras, changeable message signs, ramp meters, and traffic speed sensors. Each of these devices is connected to the centralized transportation management center in Atlanta via buried optical fiber.

When Georgia Navigator was first designed, it was state-of-the-art for its use of video cameras in gauging traffic flow, although most traffic flow observations depended on fairly low-tech sensors embedded in the pavement. Since the installation of the system, video-based systems have become the industry standard. Because Georgia

Navigator was so advanced when it was installed in 1996, even parts of the system that have not been upgraded since then are still fairly up-to-date. Georgia Navigator’s area was extended in the late 2000s to include nearly all of Atlanta’s outer belt and previously unincorporated traffic lights and ramps.

There are those who have criticized TMS and other elements of ITS, claiming that these systems have never been scientifically justified. Therefore, their implementation was based simply on the perception of various individuals about the need for optimization, instead of a scientifically proven need or some evidence that improvement is possible. Critics have also decried these systems for inherently favoring personal motor vehicles over mass transit, such as buses or rail systems, or bicycles or pedestrians.

Traffic Mitigation Programs

Traffic mitigation programs are measures aimed at a reduction of the negative effects of road transportation in urban areas through the management of traffic levels. They usually consist of regulations on the use of some links in the road network or of measures influencing travel demand, the choice of modes of transport, or the assignment of traffic to the network.

The programs address issues such as congestion, environmental quality, road safety, pedestrian mobility, and energy consumption. Despite the potential benefits, these programs face several constraints regarding their effectiveness in influencing traffic levels and behavior, as well as social and political support for their introduction.

Traffic Restriction

Traffic restriction measures limit traffic in some parts of the road network. The limitation can be permanent or temporary (valid only at specific times of the year, week, or day) and can apply to all or some vehicles, depending on their characteristics (for example, size, age, contribution to the emission of air pollutants, or license plate number).

One example of traffic restriction is the limitation of traffic in all roads and streets within a specific area of the city. This policy is known as areawide traffic restriction and is often applied in the city center, with examples found throughout Europe. The restriction may apply to private vehicles only or to all motorized traffic. However, in most programs, the restricted links are open to local residents and, at some times of the day, to freight vehicles.

These measures are introduced as a means to reduce traffic levels and congestion in areas with high concentrations of travel destinations for work, study, or shopping trips, and where the road capacity is insufficient to meet the demand for road space. The policy also promotes the mobility of pedestrians, as the limitation of road traffic is usually applied in conjunction with the “pedestrianization” of some streets.

The reduction of traffic has benefits in terms of reduced accident risk, air pollution, and noise in the areas of application. The introduction can then be justified in terms of social equity, because, in many

cities, the central areas are inhabited by populations particularly vulnerable to deteriorations in pedestrian mobility and environmental quality, including the elderly, low-income populations, and racial minority communities.

Road space rationing is another example of traffic restriction policies. In this case, the restrictions are based on vehicle license plate numbers and apply on certain days of the week only. The measure has been used in Athens, Greece, several Latin American cities (such as Mexico City; São Paulo, Brazil; and Santiago, Chile), and more recently in Beijing, China. The restriction usually applies to road links where congestion is particularly high, such as the main commuting corridors from suburbs to major centers of employment.

Empirical studies show that the application of road space rationing leads not only to the reduction of congestion in the restricted links but also to reductions in the emission of air pollutants at the city scale. By restricting the possibility or reducing the convenience of car trips, the policy may also contribute to a modal shift to public transit or non-motorized modes.

Despite the potential economic, social, and environmental benefits, the introduction of traffic restriction measures often meets with strong opposition. Some of the arguments deal with the loss of freedom for road users, who are forced to reduce the number of trips, change to alternative means of transport, or use alternative routes—leading to increased time and monetary costs and losses in comfort and convenience. Critics also raise doubts regarding the effectiveness of the policy in decreasing traffic-related problems at the city scale, because traffic levels may increase in the roads used as alternatives to the restricted links. In the case of area restrictions, the policy may also lead to an increase in car parking space or in cruising for parking at the fringes of the areas of application. Critics also question the effects of the policy on retail business and employment in the areas of application.

Area Licensing in CBD

Area licensing programs control road use in a section of a city by allowing access only to licensed users. The licenses are granted in exchange for a fee but can also be distributed for free to residents or workers in the area of application of the policy. Bus traffic and other means of public transportation are

often exempted. Area licensing programs are usually applied in central business districts (CBD) or in other areas with high business concentration, employment, and services.

The oldest example of this policy is the Singapore Area Licensing Scheme. The program was introduced in the Singapore city center in 1975. Free access was granted to some vehicle types, including buses, taxis, and high-occupancy vehicles. The program was later extended to a series of expressways outside the city. The system was converted to an electronic road pricing program in 1998.

Other cities have since adopted similar programs, usually called “cordon tolls” and based on the collection of fees for entrance into the city center by a vehicle. Several European cities have implemented cordon tolls, including London; Oslo, Norway; and Stockholm, Sweden.

Area licensing programs address similar objectives to areawide traffic restriction policies, namely, the reduction of congestion in areas where road

capacity is insufficient to meet high volumes of traffic. The restriction of the number of licenses granted reduces travel demand and increases average speeds in the areas of application of the policy. The reduction of traffic levels also improves local environmental quality. Studies evaluating the impacts of the Singapore Area Licensing Scheme provide significant evidence of the benefits of this type of policy, including the stability of traffic, congestion, and emissions of air pollutants.

Area licensing is a type of road pricing program, and, as such, it shares some of the advantages and disadvantages of economic-based policy instruments. The granting of licenses is a source of revenue for the transport authority, which can be reinvested in the improvement of the public transit network. On the other hand, the application of a fee to use roads has important social equity implications because it prices out some users of the system.

Because of these disadvantages, the introduction of area licensing programs and related policies

The earliest known traffic restriction measures were implemented by Julius Caesar in Rome in 45 B.C.E. Carriages and horse-drawn carts created congestion problems, so the center of Rome was off-limits between 6 A.M. and 4 P.M. The policies of today serve the same objective: the reduction of a negative impact generated by peak urban travel demands. As seen in the sky above this typical Southern California rush hour traffic jam, air pollution is one of those negative impacts.

often lack the necessary social and political support. This explains the failure in the introduction of some projects, such as the Edinburgh, Scotland; and Hong Kong, China, electronic road pricing programs.

Traffic Restraint

Traffic restraint programs usually involve a regulated reorganization of city traffic to discourage the use of private vehicles and to promote public transportation and nonmotorized mobility. The programs are usually presented as an alternative to both regulatory instruments restricting traffic and to economic instruments (such as area licensing programs and road pricing) because of the limitations on the social and political feasibility of these policies. The main objective of traffic restraint programs is to influence people's travel decisions in order to arrive at a desirable level of total traffic or modal split between motorized and nonmotorized travel and between private and public transportation.

The use of traffic restraint as a strategic means to control travel demand has been used in Paris, France, since the beginning of the 21st century, with generally positive results. The program has been applied at the metropolitan level and includes several interrelated measures to make public transportation, walking, and cycling more attractive when compared with car travel. Interest in the application of some of these measures has also grown in other cities throughout the world.

A common traffic restraint measure is the reassignment of road space between various road users. This involves the reduction of the number or the width of general-use vehicle lanes and the increase of the number of bus and bicycles lanes and/or the widening of pedestrian pavements. The policy brings clear benefits to the mobility of users of nonmotorized modes and public transportation. However, inefficiencies can be created if the new lanes are used below their capacity and if congestion is increased in the general-purpose lanes.

Car use can also be limited by parking policies. This involves, for example, the reduction of the number of parking spaces, including the implementation of new bus or bicycle lanes and widening of pedestrian pavements. The increase of parking fees is another possibility for decreasing the attractiveness of car travel in urban areas. The benefits of these policies are, however, dependent on the sensitivity of car

users to the availability and price of parking. In addition, congestion and pollution may increase as some drivers spend longer times cruising for parking.

Changes in speed limits are another instrument of traffic restraint, with a growing number of examples of cities introducing speed limits of 12 miles per hour (20 kilometers per hour) or 19 mph (30km/h) in some residential areas. In recent years, the policy has started to be introduced at the level of whole administrative areas. This is, for example, the case of Islington, a ward in central London, where the entire street network has a speed limit of 20 miles per hour, including not only side streets but also main roads. The reduction of speed limits has obvious benefits in terms of road safety for car users, cyclists, and pedestrians. However, critics have expressed concern about the effect of this type of policy on overall congestion and air pollution emissions.

Traffic Avoidance

Traffic avoidance programs are policies that promote the reduction of road traffic through the substitution of some of its functions. These policies are usually subject to less social and political protest, because they do not seek traffic reduction through the direct regulation of the transport sector and, as such, they are not restrictions to the choices of households and firms in the transport market. The target of these programs can be passenger or freight travel.

Policies directed at passenger travel may aim at a reduction of the need to travel or at a change in trip frequencies. The measures are not specific to transport planning but are instead an element of policies in other sectors, such as employment, education, and public administration. One example is the promotion of programs and activities that reduce the number of total trips, such as work-from-home (also known as telework or telecommuting), distance learning, videoconferencing, Internet shopping, and electronic government. An alternative policy is the promotion of programs that modify the temporal pattern of passenger trips in order to distribute these trips evenly throughout the day and reduce congestion in peak periods. An example of this type of policy is the provision of incentives for firms to implement flexible work time schedules.

Policies can also aim at a change in the means of transportation used to access certain destinations. This is, for example, the case of measures to promote

ridesharing (that is, the use of cars or vans to transport workers accessing the same area). This policy reduces traffic levels for the same number of passengers sharing. Ridesharing trips can be organized by companies that provide vehicles and link passengers traveling to the same destination. Programs can also be organized by companies for their employees or by large retail shops for their customers.

Freight traffic can also be influenced by traffic avoidance policies. The reduction of this type of traffic is an objective of special importance in road traffic management because large freight vehicles are responsible for more congestion, noise, and air pollution than other vehicles. Public policies in this field usually aim at encouraging freight firms to shift from air and road transport to less polluting means, such as rail and water. This can be achieved by improving rail and port infrastructures or providing tax advantages to firms using these means of transport. Other policies aim at a reduction of road freight transport by promoting more efficient distributional channels, for example, by reducing the number of trips by changing scheduling and routing.

Traffic avoidance policies in the freight transport sector operate at a global, national, or regional level. At the city level, there is a smaller scope for reducing the number of trips or changing transport mode because freight transport serves a large number of businesses dispersed throughout the city. The policies, in this case, focus on creating conditions for the firms to change delivery times, with the objective of avoiding high volumes of freight traffic during peak commuting hours. This involves, for example, the restriction of freight vehicles in some areas of the city at some times of the day.

Traffic Monitoring

Traffic monitoring relies on the use of such tools as helicopters, remote video, and sensors to collect a variety of data, including the number, type, and weight of vehicles. Traffic monitoring utilizes both older intrusive technologies, such as sensors embedded in roadbeds or surfaces, and newer nonintrusive methods, such as the use of traffic helicopters and remote video cameras. Traffic monitoring occurs at the local, state, and national level in many countries and is most widely used in urbanized areas. The general public, the media, government, and traffic engineers all utilize traffic monitoring data.

Increased vehicle ownership and travel, suburban growth, and reliance on highways for commercial transportation in the post-World War II period resulted in highway construction and roadway congestion. Computing revolutionized traffic monitoring technology in the late 20th and early 21st centuries, leading to the development of nonintrusive traffic monitoring; larger, more comprehensive data sets; faster, safer, and less expensive data collection and analysis; and the design of intelligent transportation systems (ITS). These developments have also facilitated traffic monitoring in urban and metropolitan areas most prone to traffic congestion.

Data gathered through traffic monitoring can include traffic flow, vehicle and axle counts in multiple lanes, vehicle speeds in multiple lanes, vehicle weights, axle loads and spacing, intersection or ramp movement counts, the presence of and alerting to accidents or stopped or disabled vehicles, wrong-way vehicles, and other potential traffic hindrances such as severe weather. Newer traffic

monitoring technologies can detect additional data such as vehicle occupancy, points of origin and destination, and travel times. The analysis of traffic monitoring data is vulnerable to problems such as the inherent unpredictability of traffic movements.

Traffic Monitoring Methods

The use of helicopters and remote video is characterized as nonintrusive traffic monitoring systems because there is no required installation of components within the roadbed or surface. Remote video cameras are most often located on structures or poles, and are most often employed along freeways, major arteries or intersections, or other highly-traveled locations. Remote video detection systems can compare images captured from these cameras with programmed baseline images to automatically detect anomalies such as traffic congestion.

Traffic helicopters and remote video systems aid in traffic monitoring by providing real-time visual traffic information. Radio and television news and morning shows routinely employ traffic helicopters and remote video to provide real-time information and footage on daily commuter routes and potential problems, such as accidents, road closures, and weather conditions.

Sensors are considered intrusive traffic monitoring systems because they must be installed within the roadbed or road surface. Traffic engineers record, transfer, and analyze the recovered sensor data. Data samples from specific roadway sections or time allotments are extrapolated to estimate traffic information for entire roadways (or years) as a more cost-effective method than placing sensors and gathering data from every roadway section at all points of the year. Early types of sensor technology employed in traffic monitoring that are still in use include manual observation and data collection, pneumatic road tubes, and inductive loop detectors. Pneumatic road tubes record the number of vehicles passing a particular location.

Inductive loop detectors remain among the most employed traffic data collection methods. They are embedded within the roadbed and measure and record information as vehicles travel through the resulting magnetic field. This information may include vehicle speed, length, and weight, as well as the distance between vehicles.

Newer sensor technologies include strain gauges, capacitance pads, load cells, piezoelectric sensors,

and automated vehicle identification sensors. Newer in-vehicle devices are also increasingly popular tools in traffic monitoring. Radio frequency identification devices (RFID), often used for automatic toll collection, use travel time between sensors to provide estimates of vehicle speeds, while the Global Positioning System (GPS) can provide vehicle positions and speeds. RFID devices are also sometimes used for traffic light sequencing along with image processing and beam interruption systems.

Traffic Monitoring Uses

Traffic monitoring improves traffic flow and capacity while reducing traffic congestion and fuel consumption. It also aids in safety and improves emergency response times to accidents, disabled vehicles, and other incidents. Personal and community benefits include improved navigation, optimal route planning, access to real-time or almost-real-time traffic information, reduced fuel costs, and reduced stress and related incidents of so-called road rage. Traffic monitoring data can also be commercially marketed.

Traffic engineers use traffic monitoring data in the complementary field of traffic control and calming. The data helps traffic engineers develop and implement such strategies as traffic signal timing, ramp metering, high-occupancy vehicle (HOV) systems, rapid incident response, congestion pricing schemes, and roadside assistance programs. Traffic engineers and urban planners also utilize the data in urban design, roadway planning and construction, and traffic emissions reductions and other environmental programs.

Traffic reporting allows media outlets, such as radio and television news programs, to provide near-real-time traffic information for their listeners and viewers. Traffic reports are especially prevalent during the morning and evening rush-hour periods. Traffic helicopters sometimes help break local or national news through coverage of traffic chases involving law enforcement. Media organizations in large national or metropolitan markets often employ their own traffic helicopters, while media organizations in smaller markets often rely on private contracting services to reduce costs.

Various traffic monitoring technologies are often developed and employed based on cost/benefit and cost-effectiveness analyses, because they often require both financial and personnel expenses. Cost

and risk analysis looks at initial and ongoing financial investment, safety issues, technological and other challenges, and environmental impacts. The economic crisis that began in 2008 and its resulting budget constraints, coupled with public pressure for cost-cutting measures, have reduced funding and staff in many state and local governments, leading to cuts in programs such as traffic monitoring.

Intelligent Transportation Systems

Computing advances, most notably in the fields of microcomputing, wireless communications, and advanced vehicle electronics, led to the development of ITS technologies, which began to influence the traffic monitoring and control fields by the early 21st century. Real-time traffic monitoring data and properly equipped vehicles are essential to ITS functionality. ITS uses include automatic traffic law enforcement devices, such as red-light cameras, speed alerts, and automatic license plate number recognition, and electronic systems, such as informational highway electronic bulletin boards.

In-vehicle uses include the selection of optimal routes, the availability of electronic maps and other traffic data through GPS or other systems, and emergency vehicle assistance notification systems, such as OnStar. New ITS technologies and growing use of traffic applications for smartphones, which allow drivers to directly share information through mass social networks, may reduce future demand for media traffic monitoring and reports.

Potential ITS features utilizing traffic monitoring data include completely automated vehicles and infrastructure systems, the roadside-to-vehicle transmission of traffic and related conditions, and car-to-car communications systems. Satellites and other technologies also have potential use in future traffic monitoring and ITS.

ITS technology is emerging on the global stage as well. Networks such as ERTICO-ITS Europe, ITS Japan, and ITS America promote ITS development and implementation in their countries or regions and jointly host an annual ITS World Congress.

Traffic Noise Abatement

Noise associated with transportation has progressively become a nuisance to communities along roads. As transportation of people and goods continues to grow, roads expand and noise levels rise. Transportation agencies have become more environmentally sensitive and ready to deal with pollution problems, including noise.

A number of factors affect the level of traffic noise, such as vehicle speed, terrain, grade, surface absorption, and shielding provided by walls, fences, buildings, or even dense vegetation. The most frequently used noise abatement measure has been the construction of noise barriers on the side of the road. Such barriers are normally built along highways that carry heavy traffic in urban areas, where noise pollution is likely to be higher and affect more people.

Because of their high cost, however, traffic noise barriers are not typically placed in rural areas, where not as many people are affected by noise, or on low-volume roads, where the noise levels are not consistently high. Even for residents and businesses near the barriers, however, the noise abatement is only effective in the acoustic shadow of the wall. Other receivers of the sound are affected as much as they were without the barrier.

In recent years, there has been a growing interest in designing and constructing quieter pavements to abate traffic noise by reducing the noise at the source. Some alternative abatement measures include the use of buffer zones, managing of traffic, and installing noise insulation in buildings.

Noise Barriers

Noise barriers are normally solid-wall structures built between the highway and the impacted activity area. Barriers do not eliminate the noise; they only reduce the noise levels for certain benefited receivers (people within hearing distance), normally those in proximity to the road. Barriers are especially effective for those receivers situated directly behind it, who can experience a decrease in noise level of typically 5 to 10 dBA (A-weighted decibels).

Noise barriers are not effective for homes on a hillside overlooking a road or for buildings that rise above the barrier; the barrier must be high enough and long enough to block the view of the road.

Common materials for barrier construction are concrete and masonry; other materials are metal and acrylic. Such barriers are mostly reflective. Absorptive materials can also be used and these include panels with mineral wool or other fibers inside them. The height, length, and material are key components to the effectiveness of the barrier. Openings in the barriers, such as those designed to allow access to side roads or driveways, decrease their effectiveness.

Many barriers reduce visibility and lighting; in such cases, transparent materials can provide a solution. Barriers could also present a problem for businesses along the road by restricting views and access by customers. Normally, transportation agencies invite public involvement in the decisions about barrier design and construction.

Quieter Pavements

The sound generated by highway traffic comes from various sources, namely, tires, pavement, engines, exhaust, and brakes. At highway speeds, tire/pavement noise is the major component of traffic noise. By utilizing quieter pavements, the noise is eliminated at the source. The properties of tires and pavements have a significant role in noise generation.

Pavements are designed for safety and durability; it has been shown that both asphalt and concrete surfaces can be designed to be quieter. There is a wide variability in pavement characteristics, resulting in a broad range in noise levels generated by traffic; the main pavement properties linked to noise are texture, porosity, and stiffness.

Texture is important for proper friction and skid resistance, which are basic safety features of all pavements. Small and smoother textures are usually related to quieter surfaces. The voids in the

pavement provide drainage to the surface, another fundamental safety characteristic, but the voids also absorb noise. The stiffness of the pavement surface has an effect on noise, and harder pavements are generally louder. Softer materials, such as rubber, are sometimes included in pavement mixes to make them quieter.

Asphalt pavements that are open-graded are generally quieter than their more conventional dense-graded counterparts. Open-graded asphalt mixes are generally characterized by a large percentage of one size of coarse aggregate (usually 1/2 or 3/8 inch maximum particle size), little or no fines, and a high percentage (15 to 25 percent) of air voids in the mix. The voids provide channels between the angular surfaces of the aggregate to allow rapid drainage of surface water. This prevents hydroplaning and provides maximum skid resistance, while also reducing splash and spray, improving visibility of stripes and pavement markers, and reducing glare from headlights while driving at night under wet road conditions.

Studies have found that open-graded surfaces can reduce roadside noise levels by 3 to 7 dBA, when compared to dense-graded asphalt pavements. A disadvantage of open-graded pavements could be the decline in their acoustic durability over time, which sometimes occurs because voids tend to get clogged by debris and compacted by traffic loads.

Concrete pavements can be made quieter by using proper texturing and finishing techniques after the concrete has been placed. The use of common texturing procedures, such as transverse tining, typically results in loud pavements; instead, texturing alternatives, such as carpet drag and diamond grinding, have produced quieter surfaces.

Other Noise Abatement Measures

Buffer zones are areas of undeveloped open spaces between a highway and the residences. Agencies can purchase land for noise abatement. However, buffer zones are not frequently used, because a large amount of land is typically necessary for them to be effective, and in many cases, residences already exist close to the roads. Vegetation can be used to mitigate noise, if it is dense, high, and wide enough to protect the receivers. However, it takes about 200 feet of dense vegetation to audibly reduce traffic noise, and its effectiveness is therefore limited. Trees provide a visual shield and some

psychological benefit, but are not acoustically comparable to a solid barrier.

Certain methods of traffic management can reduce noise levels. Reduction of speed limits can be implemented as a way of mitigation; a 10 mile-per-hour reduction in speed normally represents a 2 to 3 dBA decrease in noise levels. Trucks are usually responsible for a main part of traffic noise. Typically, one truck generates the same acoustic energy as 10 passenger cars. Trucks can be prohibited from certain roads, or they can be permitted to use those roads only during daylight hours. Traffic lights can be changed to smooth out the flow of traffic and eliminate the need for frequent stops and starts.

Mitigation measures can also be performed by affected receivers, which include insulating, caulking, replacing windows and doors, installing weatherstripping, utilizing air conditioning as an alternative to opening windows, and making other improvements to private structures. Finally, the geometric design of the road could be tailored to reduce traffic noise, as braking, accelerating, climbing, and turning will all increase noise to varying degrees.

psychological processes underlying that behavior. While many external factors influence traffic efficiency and safety, internal factors are also significant. There are several models that are drawn from social psychology, such as planned behavior, driver stress, risk compensation, and personality theory. These and other theoretical aspects of psychology are applied to improve traffic mobility and increase safety on the roads.

According to the National Highway Traffic Safety Administration's (NHTSA's) "Traffic Safety Facts 2010," approximately 5,419,000 crashes (fatal and nonfatal) occurred in the United States in 2010. According to the International Association for Applied Psychology (IAAP), there are approximately 1.3 million fatalities on the world's roads every year; estimates of annual nonfatal crash injuries vary between 23 million and 34 million people.

Expanding Field of Study

Traffic psychologists strive to understand the mechanisms that may explain a driver's dynamic behavior. Areas of research in this field include variables that affect traffic relative to driver behaviors, such as decision making, demographics, distraction and inattention, drug and alcohol use, training and experience, habits, familiarity with vehicle and environment, fatigue, spatial cognition, perception-reaction time, and panic responses. Another large area of research involves risky behaviors when driving, such as hurry, social pressure, narcissism, competition, anger, aggressiveness, thrill seeking, listening to music, talking on the phone, and texting.

The study of traffic psychology also encompasses possible countermeasures that can be used to reduce risk from these behaviors. Prosocial behaviors, such as courtesy and cooperation, and socially influenced behaviors, such as conformity, are also being studied. Traffic psychologists are highly motivated to seek greater understanding of human behaviors and to uncover ways of reducing the global toll of death and injury on the world's roads. This field of applied psychology continues to gain in relevance and importance.

Global Awareness

The 5th International Conference on Traffic and Transport Psychology (ICTTP) took place in Groningen, the Netherlands, in August 2012. (The 6th International Conference will be in Brisbane,

Traffic Psychology

Traffic psychology is a widening field in psychology that studies the behavior of road users and the

Australia, in 2016.) Partially sponsored by the International Association of Applied Psychology (IAAP), the symposium focus was on “Traffic and Transport Behaviour: Interaction Between Theory and Practice.” Presentations at the conference included research in the areas of behavioral adaptation, elderly drivers’ behaviors, risk and hazard perception, driver attention and road design, effects of personality, gender, and age on driving behaviors, road safety education, and behavioral modeling and adaptation.

Another internationally known group that is devoted to the study of driving safety and psychology is the Global Road Safety Partnership, initiated by the World Bank Group in February 1999. The partnership is dedicated to the sustainable reduction of road crash death and injury in low- and middle-income countries, which suffer 90 percent of the 1.3 million annual deaths and more than 30 million serious injuries that arise from road crashes.

Applications of Psychology to the Modification of Driver Behaviors

Psychologists generally divide human learning and behavior into three domains: cognitive behaviors (mental skills or knowledge); affective behaviors (feelings and emotions or attitude); and sensorimotor or psychomotor behaviors (manual or physical skills).

Studies and research on cognitive behaviors deal with data recall, comprehension, and application of knowledge. Examples of some of these behaviors as they relate to driving would be evaluating, interpreting, and applying information and justifying situations. Affective behaviors, on the other hand, deal with emotions, values, and motivations. Examples of these behaviors as they relate to driving would be selected attention, recognizing responsibility, and prioritizing the taking of risks.

Sensorimotor or psychomotor behaviors deal with sensory input, environmental cues, and perception or awareness. As related to the study of driving behaviors, these would include reaction times, mechanisms or learned responses, complex responses (learned skill sets), and adaptations or modifications.

In the past, research in traffic psychology has used engineering perspectives focused on road and motor vehicle design to enhance safety outcomes of driving. Early studies in traffic psychology addressed driver error, primarily in areas of driver

Traffic psychologists study the behavior of drivers in the hope of reducing traffic accidents. Behavior research in the field deals with subjects such as personality and gender differences, age and skill differences, attention, and violation of traffic rules.

impairment caused by inattention, fatigue, and drug and alcohol use. Currently, focus is on a broader set of psychological variables, such as perceptual styles, personality traits, decision-making skills, and attitudes and motivations. Present research shows that factors contributing to driver behavior include age, gender, education, driver type, risk-taking personality, perceived risks of traffic violations, and acceptance of risk for traffic violations. Important predictors of intentions to commit traffic violations are found to be risk perception, risk acceptance, past behaviors or habits, and perceived control.

Approaches that may be applied to address and modify driver behavior include stricter enforcement strategies, incentive programs that increase drivers’ awareness of risk (and decrease their willingness to accept risk), and compulsory driver training or rehabilitation courses. Research at present is rigorously focused on developing more strategies to modify driver behaviors.

Aggressive Driving Behaviors

Traffic and driving behaviors are frequently studied in conjunction with accident research in order to assess

causes of accidents. While it is unknown exactly how many fatal and nonfatal traffic injuries are caused by aggressive driving, estimates indicate the number to be substantial. This view is based on the types of violations committed by drivers of vehicles involved in crashes as reported by law enforcement agencies to be the contributing factors of the crashes.

By law, aggressive driving is defined as a progression of unlawful driving actions such as speeding, improper or excessive lane changing, or improper passing. The aggressive driver fails to consider the human element involved. There is a difference between aggressive driving and true road rage. Aggressive driving is a traffic offense; actual road rage is a criminal offense. Road rage is defined as an assault with a motor vehicle or other dangerous weapon by the operator or passenger(s) of a motor vehicle or an assault precipitated by an incident that occurred on a roadway. Road rage requires willful and wanton disregard for the safety of others.

Aggressive driving is sometimes considered road rage by the media and by those offended. Many people on the road have experienced other drivers who weave recklessly in and out of traffic, drive too fast on crowded highways, tailgate, scream out their windows, use obscene gestures, or even force other vehicles off the road.

Because driving is so embedded in our recent culture, some individuals feel a sense of entitlement to the road. The anonymity of being behind the wheel gives aggressive drivers a false sense of control and power; therefore, they seldom take into account the consequences of their actions.

Countermeasures

In an NHTSA survey, participants ranked the following countermeasures, in order, as most likely to reduce aggressive and unsafe driving behaviors: (1) more police assigned to traffic control, (2) more frequent ticketing of traffic violations, (3) higher fines, and (4) increased insurance costs.

Increased police enforcement was rated number one both for effectiveness and as a measure acceptable to the public to reduce unsafe and illegal driving.

There are a number of road rage tests and driver personality quizzes available for the public. The designers of these questionnaires are obviously looking for traits of unmanaged anger. Participants answer questions about (or rate) behaviors that they may have engaged in or thought about engaging in.

Examples of the behaviors test takers are asked to consider include mentally condemning other drivers, verbally denigrating other drivers to passengers in the car, closing ranks (using the stare-ahead strategy) to deny someone entering your lane, giving another driver a dirty look, speeding past another car or revving the engine as a sign of protest, preventing another driver from passing, tailgating or pressuring another driver to go faster or get out of the way, fantasizing about physical violence against another driver, yelling at someone through the window, or making a visible obscene gesture at another driver.

If the test uncovers a proclivity for public displays of aggression on the road, the driver is given various types of advice, most of which encourages the participants to think ahead and modify their own behavior. A few techniques are suggested, such as relaxation breathing, listening to music, and avoiding driving when upset or fatigued.

To modify one's behavior, it is also suggested to choose one behavior at a time to practice. This could mean any of the following modifications: leave home 15 minutes earlier than usual (to avoid time pressures), increase following distance behind vehicles, drive less frequently in the passing lanes, reduce cruising speed by 5 to 10 miles per hour, consciously avoid getting angry when forced to brake by another motorist, avoid feeling hostile when progress is impeded by congestion, and/or avoid retaliation when another driver insults you.

Traffic Safety and Risk Assessment

An alarmingly high number of vehicle accidents result in serious injuries or death, which makes assessing the risks involved with traffic ever important. The National Highway Traffic Safety Administration (NHTSA), a component of the U.S. Department of Transportation (USDOT), maintains that safety is its primary focus, resulting in a constant focus on data collection and evaluation to implement strategies to reduce and prevent the number of crashes and fatal accidents that happen on the road. This occurs through legislative strategies (laws), law enforcement, and driver-awareness campaigns.

Speeding and Aggressive Driving

Exceeding the speed limit by more than 10 miles per hour (mph) is classified as speeding by NHTSA. Speeding often coincides with aggressive driving, which is defined as “an individual who commits a combination of moving traffic offenses so as to endanger other persons or property.” Drivers, with regard to speeding, are divided into four categories:

1. Incidental and non-speeders, who speed on a small number of trips and for only a small portion of the trip
2. Situational speeders, who speed a lot on a small number of trips
3. Regular and casual speeders, who speed a small amount on a large majority of their trips
4. Habitual speeders, who speed regularly for large portions of their trips

Studies show that it is fairly common for drivers to speed to some extent on any given trip, although some drivers never do at all. It has also been found that weekend and morning trips are most commonly

associated with speeding. Despite the fact that young males have been proven to speed more than other demographics, speeding itself is not limited to any gender or age demographic. Similarly, speeding is not defined by a driver's attitude toward reckless driving or limited to rural or high-speed roadways.

There are many situational factors that influence speeding, including the type of trip, length of trip, presence of other passengers, a driver's propensity to run late, the presence of law enforcement, opportunity, road conditions, and geographic location. Focus groups show that drivers consciously choose to speed, despite knowing safety or speeding tickets could be a potential consequence, which shows how strong a role situational factors play.

Speeding overall is certainly not limited to certain demographics, although some may be more inclined to speed than others. Young males, as previously stated, are the most likely to speed, and males as a whole speed more than females, in particular, older females. Because no demographic alone is immune to speeding, it is believed that personal traits, such as attitudes toward driving, or situational factors influence all demographics. The four classes of speeders are not well defined by demographics, because drivers from all demographics are somewhat equally represented in all groups.

Location and type of vehicle being driven play a large role as well. One study noted that in Texas, driving a truck or a sports car puts you at a greater risk for speeding, but the opposite was found in Seattle. Although not true in Seattle, the trend in Texas is that being associated with affluence (as symbolized by those vehicles) led to greater instances of speeding. Geographical opportunity and regional attitudes influence these drivers.

Although difficult to measure, driver beliefs and attitudes are found to be significant predictors of speeding. Factors such as aggressive driving, inattentive driving, and bad driving habits are often associated with increased risks of speeding. Some factors, however, that logically would be associated with speeding, such as making frequent driving mistakes, prove to show inexperience with driving and therefore less speeding. The following three factors sometimes correlate with speeding:

1. Reckless driving, which includes dangerous violations such as driving drunk, racing, and tailgating

2. Road rage, which shows hostility and anger toward other drivers
3. Dangerous driving, which includes risk-taking behaviors such as running yellow lights and cutting off other drivers.

Traffic Crashes and Risks

Traffic crashes and collisions occur when a vehicle hits another car, person, object, or debris. Although often resulting in injury to passengers or damage to vehicles, accidents can, and often do, cause death, which makes measuring, assessing, and preventing their cause significant.

NHTSA developed the Fatality Analysis Reporting System (FARS) in 1975 to create a database of fatal crashes in the United States and their characteristics. The goal of FARS is to evaluate the effectiveness of safety standards and provide objective solutions for failures in those standards. Data is collected by all 50 U.S. states and must involve a motor vehicle traveling a road that is designated for motor vehicle travel and include the death of a person. To date, FARS has collected data on nearly 1 million vehicle fatalities.

This data collection is critical to NHTSA and USDOT's overall mission to improve safety and reduce the number of traffic-related crashes and deaths. Human factors in accidents include behavior, impairment, and limited visual accuracy. Fifty-seven percent of crashes are caused by factors related to the driver, according to a 1985 study. Overconfidence in one's driving ability is very often the source of factors related to driver-caused accidents.

The Federal Highway Administration has evaluated risks involved in traffic accidents. Evidence shows that, in relation to speed, the following hold true: (1) the risk of having a crash is increased for both vehicles, (2) the risk of being injured increases exponentially with speeds much faster than the median speed, (3) the severity of a crash—and potential fatality rate—depends on the vehicle's speed upon impact, and (4) crashes related to speed involve a speed rate that is too fast for current driving conditions. Reducing speed limits and their enforcement normally does reduce the risk of crashes, although data can be contradictory. While some studies show a correlation between reduced speed limits and reduced number of accidents, others show that speed limit reductions may just

reduce the speed of drivers but not necessarily their risk or potential to crash.

Risk assessments are particularly significant to the auto industry and auto insurance industries. Many studies have found that despite improvements in automobile design, the result has not been a significant decrease in accidents, injuries, or fatalities.

Antilock brakes, for instance, have proven in many studies to seemingly encourage drivers to drive faster, follow the car in front of them closer, and brake as late as possible. However, one safety device has saved countless lives. A 2007 study by the NHTSA showed that in the nearly two decades between 1985 and 2002, there was a significant reduction in the fatality rates for vehicle occupants who wore seat belts.

The NHTSA also tracks data on driver impairment, such as from drugs or alcohol. In 2010 alone, more than 10,000 people died as a result of alcohol in motor vehicle accidents—one person every 51 seconds. Physical impairment, such as auditory or sight problems, sleep deprivation, and age, in particular with novice young drivers and elderly drivers, play significant roles, as well.

Traffic Signal Priority

Traffic signal priority (TSP) is a tool to improve service and reduce delays for priority vehicles, usually mass transit vehicles, at intersections controlled by traffic signals. The sensors at intersections detect an oncoming bus utilizing an onboard device and make adjustments in the signal timings to move the bus through the intersection as quickly as possible without adversely impacting the rest of the traffic. TSP allows for faster, more reliable, and more cost-effective movement of transit vehicles in a congested corridor. It could be used for bus, tram, or light rail lines.

Deployment of TSP is an essential aspect of bus rapid transit (BRT) systems, which rely on fast and reliable service. It should be noted that TSP gives priority, not preemption, to transit vehicles. While preemption interrupts the regular signal process, priority only modifies the process to better accommodate the transit vehicle. There are many technological aspects that need to be thoroughly understood and analyzed before arriving at a decision on what type of TSP system needs to be implemented. Its use is common in Europe and is rapidly growing across North America.

Benefits of TSP

There are several benefits of using TSP, including improved transit reliability, reduced transit travel times, reduced stops (less wear and tear on equipment), increased rider comfort, and reduced emissions. Because TSP allows for smoother flow of transit vehicles, they can move from point to point, as well as to final destinations, on time more often.

Research shows that this increased reliability is a critical need for any transit to become successful. Because the vehicles are sitting on red signals for a much smaller amount of time, the trips can be faster, making transit attractive for riders. This reduction in travel time can also allow for fewer buses to serve a particular route, which can result in reduced operating costs. When vehicles do not stop at every signal, the wear and tear on the vehicle and equipment, as well as that of the pavement, is reduced.

Vehicular emissions result from a combination of distance traveled, speed, acceleration, deceleration, and fuel, among other factors. A smoother flow facilitated by TSP can give the vehicles a relatively constant speed and less need for frequent

stops, acceleration, and deceleration—resulting in reduction in emissions. An aggressive level of prioritizing transit over general traffic, as seen in many European countries, can reward transit usage and help reduce traffic congestion.

The cost of TSP is mainly attributed to equipment. Sensors and communication equipment need to be installed at intersections, as well as in vehicles. Complex designs and greater functionality can increase the cost. Another important expense is to upgrade the signals and controllers. Further cost is incurred in setting up control centers and training personnel.

TSP Methods

TSP can be employed on a location-to-location basis or on a systemwide basis. Systemwide TSP requires the employment of advanced technologies—one example is an automated vehicle location (AVL) system.

Passive TSP techniques involve optimizing signal timing or coordinating successive signals on a corridor. This technique allows for longer green time on the main street and a series of signals that stay green, which will allow the transit vehicle to move along smoothly. This can perform well when there is a significant amount of transit service on a street with high frequency. Passive techniques are cost-effective measures because they do not require specialized technology (for example, bus detectors).

There are several TSP treatments possible, including passive priority, early green, green extension, actuated transit phase, phase rotation, phase insertion, and adaptive real-time control. The most commonly used TSP strategies for buses operating in mixed flow are green extension and early green.

The early green strategy is usually applied to reduce the time for a bus to wait at a red traffic signal. It shortens the green time of other road approaches to expedite the return to green for the approach where the presence of a TSP-equipped vehicle has been detected.

Green extension is applied to keep the green phase running until the bus approaching the intersection can go through. There will be a preset maximum value for the time of extension so as not to disrupt other approaches severely. This means that the green extension is only for a bus that is fairly close to the intersection. Green extension and early green

strategies can be employed together to maximize the time for transit vehicles within the total signal phase.

Actuated transit phases are displayed only when a transit vehicle is detected at the intersection. For example, a left turn signal will operate only when there is a bus waiting to turn left in a bus-only lane. In such circumstances, transit signal faces look different from a standard green/yellow/red face to avoid confusion with the signals for general traffic.

The phase-rotation technique shuffles the order of signal phases so that transit vehicles arrive during the phase they need. For example, protected left turn phases are usually followed by the adjacent through phases. If the sensors detect a bus coming into the left turn lane that will not be able to get through the upcoming left-turn phase, the signal controller system can allow the through movement first and shift the left turn phase so that the bus will have time to get into position for its upcoming left turn. The phase-insertion technique allows the controller to insert a special priority phase within the normal traffic signal sequence. For example, a second left turn phase could be employed for an approach if there is a bus detected toward the end of through movement. Adaptive/real-time TSP strategies provide priority while simultaneously trying to optimize given performance criteria, such as person delay, transit delay, vehicle delay, or a combination. In this case, the signal timings will be adjusted based on the arrival time of the bus, thus reducing the overall impacts on other vehicles.

TSP Planning and Implementation

TSP project planning includes a number of steps that are common in technology implementation. In the first stage of project planning, the needs for TSP, stakeholders, operational requirements, locations (intersection and corridors), and alternatives need to be identified. Involvement of all stakeholders is a key for identifying the needs and ensuring buy-in of all parties. Smooth functioning between traffic operators and transit operators is critical. Roles and responsibilities of each stakeholder must be spelled out clearly. It is necessary to decide if the TSP system will be integrated into an intelligent transportation system (ITS) regional architecture or any existing or proposed AVL systems. If the implementation of the TSP system could be coordinated with any planned upgrading of signal systems, the project could be achieved more cost-effectively.

The clarity on geographical coverage of the system is important to arrive at decisions.

The project design stage requires identification of detailed data of existing systems and traffic, design and engineering for central control and communications, systems components, detailed design of intersection and onboard equipment, and optimization and preparation of signal timing plans. The data needed include traffic volumes, pedestrian volumes, speed and delay studies, and various transit operational details.

Depending on the system architecture, the central control system and communication system may need to be modified. It is essential to design and implement these before moving further. Similarly, any equipment and physical changes at intersections and on the transit vehicles also need to be completed. Microsimulation models could be employed to evaluate different strategies and alternatives.

The project implementation stage should take care of procurement, installation, and verification/validation. The operations and maintenance stage should ensure proper monitoring and management of performance, not only of the TSP system, but also the traffic itself. Detailed procedures should be established to ensure proper operation of the system. Periodic maintenance activities also need to be addressed. Evaluation of the system through detailed studies and data collection is necessary to get feedback on the performance and to make any necessary changes once the system is in place. This feedback can also be used to improve transit scheduling.

TSP System

Mature TSP systems involve the interaction of transit vehicle, transit fleet management, traffic control, and traffic control management. Vehicle detection, the priority request generator (PRG), the priority request server (PRS), and TSP control are the important functional applications of the system.

Detection systems sense an incoming vehicle and deliver data such as the location and arrival time to a device. This device is connected to the PRG, which can be located in the transit vehicle, the transit management center, the traffic management center, or the traffic signal control system that is equipped with wayside transit vehicle detection. The PRG will then request priority from the traffic control system and triage multiple requests as

necessary. The PRG is linked with the PRS through specific communication systems. The PRS is contained within the traffic control system and processes the requests for a range of TSP strategies. TSP control incorporates traffic and transit TSP functions in both the transit management and traffic control management systems.

The traffic signal control system is responsible for acting on the priority request and making any applicable changes to the signal indications via the local traffic signal controller. The interface between transit vehicles and traffic signal control systems is central to the operation of a TSP system.

The four main components of the traffic control system are the hardware, software, vehicle detection system, and communication systems. Main controller types used in the United States and Canada are electromechanical controllers, National Electrical Manufacturers Association (NEMA) controllers, Type 170 controllers, and advanced transportation controllers. The controllers might or might not come with associated software.

The vehicle detection can be achieved with hard-wired loop detection, infrared detection, sound-based detection, radio-based detection, and Global Positioning System (GPS)–based detection.

Hard-wired loop detection systems consist of a transponder attached to the underside of the transit vehicle and a vehicle detection receiver that integrates with the signal controller. The system typically consists of an infrared strobe emitter located on the transit vehicle, infrared detectors located at each intersection, and a “phase selector” interface within the traffic signal controller cabinet that relays the message to the traffic signal controller.

A sound-based detection system consists of emergency siren detectors and digital sound-wave recognition systems. Radio-based detection systems consist of radio frequency (RF) transponders mounted on the transit vehicles and RF-tag readers installed upstream of the signalized intersections for detection. There are two types of communications in a TSP system: vehicle detection communication and communication between intersections and a control center. The vehicle detection systems are described above. Typically, intersection controllers and/or the central end are interconnected by means of a physical connection consisting of fiber-optic or copper cable. Newer systems utilize

Traffic signal priority (TSP) involves optimizing signal timing to create a smooth flow of traffic along a transit route. This optimization improves service and reduces delay for mass transit vehicles at intersections controlled by traffic signals.

wireless technology, which eliminates the need for expensive conduit and cable connections between intersections and the control center.

TSP Today

More than 50 transit agencies in North America have implemented TSP systems. Though TSP was implemented as early as 1985 (Charlotte Area Transit), the majority of TSP deployments were completed in the late 1990s and after 2000. The most common bus TSP application is a system that operates in mixed traffic on four- to six-lane arterials. Some BRT systems and light rail transit (LRT) systems also employ TSP. In most places, the systems are in place on one or two corridors only.

The number of signalized intersections with TSP functionality ranges widely, from one or two intersections to more than 1,000 intersections in large metropolitan areas. The bus stop locations are a mixture of near- and far-side locations. (Near-side stops are on the approach side of the intersection while far-side stops are on the departure side of the intersection.)

A large number of agencies use NEMA controllers and associated software. The vehicle identification

systems are either optical vehicle detection systems or loop-based detection systems. The TSP systems are increasingly being employed by transit agencies. Though there is a large up-front cost associated with implementing such systems, the experience shows that the cost is worth it compared to the benefits of a reliable transit system, better functioning of regular traffic, and overall improvement in travel experience.

of lights that corresponds to a certain movement in the intersection.

A phase is a set of signal groups that corresponds to a certain set of movements that have the right of way during the phase's green time. These movements are chosen to proceed concurrently without conflicting with other traffic streams. A signal cycle is completed when each phase has been served once, hence the name *cycle time* (also known as cycle length). Signal-control algorithms are typically designed to optimize the traffic flow using the phase scheme, the split, and the offset settings. The phase scheme determines the signal groups that have the right of way and their corresponding order in the cycle.

A split represents a distribution of the cycle time to the individual phases; in other words, this represents the green time allocated to each phase. An offset refers to the time shift—with respect to a reference point in time—of the start of a new cycle along a sequence of intersections. Offsets have been efficiently used to achieve progression along a certain corridor by creating a "green wave" for the vehicles traveling in one direction along this corridor, to minimize the number of stops and waiting times at a number of successive intersections along the corridor.

The above-defined elements of a typical signalized intersection are maintained and operated by traffic controllers in the field. Traffic control systems differ in how they allocate the green time for each phase. Traffic controllers can be classified into three main categories: fixed-time controllers, actuated controllers, and adaptive controllers, adaptive being the most advanced.

Adaptive signal controllers can be categorized into four generations: first generation of control (1-GC), second generation of control (2-GC), third generation of control (3-GC), and artificial intelligence (AI)-based fourth generation of control (4-GC).

Based on reviewing the literature on 4-GC systems using Multi-Agent Reinforcement Learning (MARL)-based approaches, the studies are classified into three categories according to the level of interactions between the signalized intersections in a traffic network: independent MARL (including totally independent MARL and partially independent MARL), and coordinated MARL (including directly coordinated MARL and indirectly coordinated MARL).

Traffic Signals

A signalized intersection is designed to allow conflicting traffic movements to proceed efficiently and safely by separating the individual movements in time rather than in space. The basic unit of a traffic signal control system is the signal group, a set

Fixed-Time Control (Pre-Timed Control)

A fixed signal timing plan is developed off-line based on historical or anticipated traffic counts. The cycle length and splits are optimized off-line only once based on the traffic counts and then deployed. Thereafter, the duration and order of all green phases remain fixed and do not adapt to fluctuations in traffic demand. Fixed-time control is designed based on average historical counts, which do not capture the dynamics and randomness associated with real-time traffic flows in the field. Therefore pre-timed control is best suited for locations where traffic exhibits predictably uniform arrival patterns over a long period of time. In addition, pre-timed control systems are unable to respond to unpredicted events, accidents, and other disturbances that may disrupt the anticipated typical traffic-flow pattern.

Isolated Intersection Fixed-Control

In fixed-time control, the signal's cycle time is distributed over the signal phases based on historical or known-in-advance volumes. Between phase switches, start-up and clearance times are needed for drivers to clear the intersection, typically considered lost time as they are not fully used for traffic flow. Therefore, in one hour of traffic flow, shorter cycle times typically result in a higher percentage of lost times. Intersections with shorter signal cycles therefore operate at lower overall capacity levels.

On the other hand, the longer the cycle times, the longer the red phases, and hence the longer the queues and the longer waiting times at the intersection. They also cause longer waiting time for pedestrians. In addition, some approaches will drain their traffic faster than others and the remaining green times are not fully utilized, causing more time waste. Finding the balance between cycle time and intersection delay is not insurmountable. For known traffic flow rates, a formula can be derived to find an optimal cycle time and green splits of all phases such that the average delay for all vehicles is minimized. There are many such basic methods in the literature, including, by way of an example, the Webster method.

Progression-Based Fixed Control

In addition to timing individual intersections, bandwidth optimization methods use traffic volumes, signal spacing, and a desired travel speed to determine the optimal progression band that can be

achieved along a corridor. Examples of bandwidth-based methods include MAXBAND, ULTIBAND, and PASSER. On the other hand, disutility-based methods use a model to minimize the disutility of a specific measure such as intersection delay or the number of stops. These models are generally designed to first find a common cycle length that minimizes the overall delay in the system and then calculate the offset required for progression. Examples of disutility-based methods include TRANSYT and SYNCHRO.

Actuated Control

Unlike pre-timed signal control, actuated traffic signal control systems are responsive to traffic flow fluctuations. Actuated traffic control requires actuated traffic controllers and vehicle detectors placed on the approaches of the intersection. The actuated timing plan responds to traffic demand fluctuations by placing a "call" at the presence or absence of vehicles approaching or leaving the intersection, respectively. Once a call is received, the controller decides whether to extend or terminate the green phase in response to the actuation source.

Although the actuated signal control settings are responsive to the presence of actuation (or calls), they are less sensitive to the traffic demand (that is, number of vehicles) calling for the actuation. Actuated phases are allowed to extend up to a preset maximum. If traffic is heavy from all approaches, all phases max out and the signal operates in a pre-time-like fashion. Actuated control can be operated in one of two forms according to the designed phase detection: semi-actuated and fully actuated.

Semi-Actuated Control

In semi-actuated control, detectors are placed only on minor streets (callable phases). The main street movements are coded as noncallable phase(s); hence, activated for the entire split time every cycle, regardless of the traffic detection. The controllers are designed such that a permissive period is defined during which the controller unit allows the callable phases to be served upon a detection request. The callable phases are typically timed to maintain the minimum green time after which the green time could only be extended upon demand and to a maximum limit. Semi-actuated traffic control is best suited for locations where minor streets intersect with major streets.

Fully Actuated Control

Fully actuated control is similar to semi-actuated control; however, the detectors are typically placed on all traffic approaches, and phases could be skipped if no vehicular demand is detected. Fully actuated control is therefore appropriate for intersections exhibiting less predictable and high traffic volumes on all approaches.

Adaptive Signal Control

In adaptive signal control, signal timing actions and/or plans are continuously updated according to measured real-time traffic fluctuations and the number of vehicles approaching the intersection. Adaptive signal control parameters (for example, cycle length, phase split, etc.) are determined to achieve a certain objective (for example, minimize delay, minimize pollution, etc.), and then the traffic controller automatically implements these parameters in response to the real-time traffic flows.

Traffic flow is highly dependent on factors such as time, day, season, weather, and unpredictable events such as accidents, special events, work zones, and so forth. Such multidimensional variations in traffic flow patterns form a challenging task for fixed-time and actuated traffic control systems to efficiently operate signalized intersections. Adaptive Traffic Signal Control (ATSC), on the other hand, has the potential to be agile and “adapt” to traffic fluctuations and can therefore alleviate traffic congestion in comparison to the more commonly used pre-timed and actuated control systems.

ATSC can be categorized into four levels or generations according to their level of adaptation and intelligence. first generation control (1-GC) uses off-line libraries of signal timings, in which case the controller selects a signal timing plan from a pre-specified set of plans that are pre-optimized based on historical counts. Compared to 1-GC, the second and third control generations (2-GC, 3-GC) optimize in real time the timing plans but they are different in the hierarchy of control employed. Although still in the research stage and not yet implemented, fourth generation control (4-GC) is seen as the next generation of ATSC as it maintains the same advantages of 3-GC while addressing the issues faced in the development of 3-GC. The 4-GC systems employ artificial intelligence and self-learning techniques that are based on direct experience with the traffic environment.

First-Generation Control (1-GC)

In 1-GC, a library of prestored signal control plans is utilized. These plans are developed off-line on the basis of a variety of historical traffic data. 1-GC traffic-adaptive systems are often referred to as traffic-responsive signal control. Examples of 1-GC include TR2 (Traffic Responsive Control Mode 2) and UTCS-1 (Urban Traffic Control System-First Generation). 1-GC may plausibly operate under recurrent and defined traffic periods if random variations around the mean flows are not pronounced. In addition, incidents and unpredicted events are inevitable in transportation networks that cause traffic patterns to change substantially beyond the anticipated typical traffic flows and therefore cannot be efficiently handled by any precalculated and prescheduled timing plans. Furthermore, any pre-timed plans age with time as traffic flows change. Therefore, as traffic patterns change with time, the signal timing plans must be continually updated.

Second-Generation Control (2-GC)

2-GC ATSC employ simplified online optimization methods to dynamically adjust the signal timings (offsets, cycle time, and splits) by utilizing online surveillance information systems. In 2-GC, traffic progression along corridors is achieved in a centralized fashion. 2-GC systems such as Sydney Coordinated Adaptive Traffic System (SCATS) and Split Cycle Offset Optimisation Technique (SCOOT) overcome some of the 1-GC systems' drawbacks; they have some limitations:

SCOOT systems have been known to have a limited traffic-responsive behavior during rapidly changing conditions; 2-GC systems are centralized systems that suffer from the following limitations:

- They primarily depend on reliable communication networks to link intersections to a traffic management center. In addition, the central computer is a risky single point of failure.
- They are often not easily scalable to expand the size of the network.
- They are expensive due to detection requirements, communication requirements, and skilled labor requirements.
- They are relatively complex to operate, with many parameters to be adjusted by a human operator.

Third-Generation Control (3-GC)

3-GC traffic adaptive systems are generally similar to the 2-GC systems in terms of adapting to traffic fluctuations. However they differ in the following important features:

- They operate in a decentralized control system that offers several cost advantages over centralized control systems.
- Most 3-GC systems use dynamic programming (DP) techniques to model and solve the traffic signal control problem. DP is the theoretically ideal optimization technique for decentralized closed loop optimal control, and it captures the stochastic nature and dynamics of the traffic system.
- 3-GC systems continuously update the signal plans parameters to respond to real-time field measurements, which therefore abandon the conventional notions of cycle length, phase splits, and offsets. Such flexibility in the signal timing setup enables the controller to produce “acyclic” signal settings (i.e., the cycle length is variable).

Examples of 3-GC systems include OPAC, PRO-DYN, and RHODES. 3-GC systems have the following limitations:

- The unfeasibility of simultaneously handling/optimizing larger groups of intersections because of limitations in the optimization methods. DP methods require a state transition probability model for the traffic environment, which is difficult to obtain and maintain. Also, the number of states that could represent wide traffic conditions is typically massive and grows exponentially with the number of intersections in a group. Therefore, DP algorithms can be computationally intractable, which hinders network-wide application of the optimization method.
- The control logic for multiple intersections is only meant to achieve progression along a certain corridor (for example, a major artery) and not two-dimensional networks; a common limitation for 1-GC, 2-GC and 3-GC systems. In congested cities, two-dimensional networks of streets

(for example, grid networks) are saturated, which is commonly the case in congested downtown areas. Nonrecurrent congestion (for example, accidents, floods, snow, etc.) may also greatly affect traffic patterns in transportation networks. Therefore, the simple progression approach sought along arterials cannot be effectively applied to a two-dimensional gridlike complex network of intersections while capturing dynamic traffic patterns.

Fourth-Generation Control (4-GC)

The fourth generation of ATSC maintains the same advantages of 3-GC while addressing the issues that have faced the development of 3-GC. The 4-GC systems are principally built on self-learning capabilities using artificial intelligence. Control agents (computer programs) learn from direct experience with the environment (intersections and traffic flows) with reasonable computational requirements to be implemented in real time. 4-GC of traffic systems is still under continuous research and testing.

Reinforcement Learning

Reinforcement learning (RL) is an artificial intelligence technique that has shown promising potential for “self-learning.” RL not only achieves as much as DP but also requires less computation and does not need a perfect model of the environment. DP examines all the possible state-action combinations while RL learns from repeated direct interaction with the environment, sampling only the most common state-action combinations. RL methods consequently capture the stochastic variations in traffic flow without the need for models of transition probabilities of all state and action combinations. As an example, DP would examine all state-action possibilities and transitions in a game of chess, while RL acts like a player who learns from previous games, learning from experience.

The basic concept of RL is concerned with an agent (for example, signalized intersection control software) interacting with its environment (for example, traffic network) in a closed-loop system in which the agent acts as the controller of the process. The agent iteratively observes the state of the environment (for example, queue lengths), takes an action (for example, extends current phase or switches to another phase), and, accordingly, receives

a feedback reward (for example, delay reduction) for the actions taken and adjusts the policy (control law) until it converges to the optimal mapping from states to optimal actions (optimal policy or control law) that maximizes the cumulative reward (for example, total delay over time). Accumulating the maximum reward not only requires the traffic signal control agent to exploit the best experienced actions but to also explore new actions to possibly discover better actions in the future.

The interaction between the agent and the environment can be viewed as two processes performed repeatedly: a learning process and a decision-making process. In the learning process, the agent adjusts the policy by updating the value associated with each state-action pair using the immediate reward value and the value of the next states. In the decision-making process, the agent chooses its action by balancing exploration and exploitation using action selection algorithms.

MARL is an extension of RL to multiple agents (signalized intersections). The decentralized traffic signal control problem is a suitable domain for MARL because of the inherent dynamics and stochastic nature of the traffic system. The simplest way to extend RL to the MARL is to consider the local state and local action for each agent assuming a stationary environment, and that the agent's policy is the prime factor affecting the environment.

However, MARL in the traffic environment is associated with some challenging issues because the traffic environment is nonstationary since it includes multiple agents learning concurrently; that is, the effect of any agent's action on the environment depends on the actions taken by the other agents. For instance, what an agent at a given intersection should do depends on the neighboring intersections and the actions of their agents. Each agent is, therefore, faced with a moving-target learning problem because the best policy changes as the other agents' policies change, which accentuates the need for action-coordination among agents (not to be confused with the conventional offset coordination in signal synchronization).

Action-coordination can be achieved by considering the joint-state and joint-action for the other agents in the learning process. Moreover, given that all agents are acting simultaneously, the agents' choices of actions must be mutually consistent to achieve their common goal of optimizing the group

of intersections. Therefore, the agents require a coordination mechanism not only in the learning process but also in the decision making process to make the optimal decision from the possible joint actions. Unlike conventional traffic signal coordination that maximizes green bands, action-coordinated MARL approaches allow coordination in two-dimensional gridlike networks of intersections while capturing dynamic traffic patterns.

Multi-Agent Reinforcement Learning

In the independent multi-agent control, agents (at each intersection) act totally independently by considering local states, local rewards, and local actions.

Partially independent multi-agent control extends the first type by following one of two approaches. One approach is to take the presence of other agents into account and extend the state space of the agent to include the state of other agents, while the agent is maximizing its local reward only. Another approach is to consider a joint reward (global reward) or to exchange the reward with other agents. However, neither approach is meant to achieve explicit coordination between agents' actions.

Coordinated multi-agent reinforcement learning extends the previous types of control to include an explicit coordination mechanism that coordinates the actions of the individual strategies in real time. The agent is "aware" of the effect of other agents' actions in the network while all agents act simultaneously. In this case the coordination mechanism enables the agents in a group to coherently choose their actions from the optimal joint policy without contradicting each other. Two approaches are investigated in the literature under this category: In direct coordination, the agents—through direct interaction—are negotiating the action choice. Direct coordination mechanisms are inspired by social conventions, roles, and communication.

Researchers have included an explicit direct coordination between neighboring traffic lights using coordination graphs. The max-plus algorithm is used to estimate the optimal joint action by sending locally optimized messages among connected agents. However, the max-plus algorithm is computationally demanding, requiring negotiations between the agents to coordinate their actions through direct communication. Also, because the system performs under time constraints, this forces

the agents to report their current best action at any time, even if that action may be suboptimal.

Indirect Coordination Methods

These methods drive the agent to select actions that will likely result in the best response to other agents' actions. The probability of obtaining best response values is evaluated using models of the other agents. These models are estimated from observed actions taken by the other agents in the past, without direct interaction/negotiation among the agents.

MARLIN-ATSC (Multi-Agent Reinforcement Learning for Integrated Network of Adaptive Traffic Signal Controllers) implements independent, partially independent, and direct coordination, as well as indirect coordination methods in ATSC. Indirect coordination in MARLIN seems to be the most feasible for field implementation because it achieves the desired coordination without the complexity of direct coordination.

MARLIN uses a combination of MARL and game theory. Each signalized intersection (agent) "plays a game" with its adjacent intersections in its neighborhood. The agent has a number of learning modules; each corresponds to one game. At each module, the agent estimates a model of the neighboring agent's control policy. Finally, the agent computes a best response to the estimated neighbors' models and uses it to estimate state-action values and to decide the control action.

Conclusion

Although research is rapidly advancing in the ATSC area, and more specifically RL-based ATSC, abundant opportunities exist to further extend and enhance the system, for instance, by integrating public transit and pedestrians in the decision optimization process. In the present RL-based ATSC, transit vehicles are treated as normal vehicles, and pedestrians are granted the minimum time required to cross the intersection regardless of the presence of pedestrians or not and their numbers. However, it is recommended to conduct future research that explicitly takes transit vehicles and pedestrians into consideration in the optimization/control logic.

Transit signal priority (TSP) is a common practice that assigns intersection right-of-way to approaching transit vehicles. The underlying philosophy of TSP is based on giving priority to high occupancy vehicles including transit vehicles, as

such vehicles carry large numbers of travelers. Rightfully so, TSP gives priority to high occupancy vehicles. However, if a transit vehicle is not full or not behind schedule, then TSP may be counterproductive as it creates traffic delays without benefiting people throughput. Therefore, the proper integration of ATSC and TSP is a logical next step to achieve the synergy of both techniques.

Ongoing research is examining the incorporation of the number of people on a transit vehicle in the intersection state vector. Instead of maximizing the reward for each signalized intersection based on the number of vehicles on the approaches, the reward would reflect the number of people waiting, regardless of being in cars or on buses, which in essence, optimizes people throughput or people signal priority (PSP). This will, however, require automatic passenger counters on transit vehicles and wireless communication to the traffic controller to register the approaching number of passengers.

Pedestrians can be better accommodated in RL-based ATSC by including, for instance, a scramble phase if the pedestrian demand warrants such an installation. On the other extreme, minimum greens can be used only if pedestrians are present. To implement the above, a pedestrian actuation button should be modeled to receive calls from pedestrians and included as one of the parameters. Newer technologies are also emerging that count the number of pedestrians waiting to cross. With such technologies in place, priority could be assigned to pedestrians depending on pedestrian demand levels and hence optimizes PSP. If the number of vehicles approaching an intersection and their occupancy are known (or reasonably assumed) and if the number of pedestrians can also be measured, RL-based ATSC can be adjusted to optimize people throughput or minimize people's delay regardless of whether they are in automobiles, on buses, or on foot, which is arguably the ultimate objective.

of interacting phenomena concurrently: land use and transportation infrastructure, and transportation demand and supply are only two such examples. The timescale of transportation interventions can range from the short term (for example, minutes or hours in the case of real-time incident response) to long term (for example, years or decades in the case of forecasting the traffic of a planned freeway or rail connection). Considering the size of most transportation problems, which can range from a single intersection or corridor to a city, a metropolitan area, or a region, spatial interactions also need to be considered. It becomes apparent that these interactions cannot be dealt with easily without the help of specialized tools. Furthermore, objective and factual evidence needs to be provided in order to accompany and support related investment and policy decisions. In light of the high costs of developing transportation infrastructure, accurate forecasts of their expected impacts can play a significant role in properly allocating resources.

The field of traffic simulation has emerged over the past few decades as a response to these needs. A large number of traffic simulation models and tools have been developed during this time, ranging from simplified analytical representations of individual phenomena to integrated simulation-based models that aim to capture all aspects of traffic and traveler behavior. In order to capture these various interactions and satisfy these numerous requirements, traffic simulation tools comprise a large number of models, each of which typically has several parameters that govern its behavior.

While traffic simulation has been increasingly used in all aspects of transportation planning and operations, traffic simulation models have also received criticism. George Box famously said (decades ago), "Essentially, all models are wrong, but some are useful." While this famous aphorism might seem like a negative statement, in essence it provides valuable insight into the benefits and limitations of traffic simulation.

Traffic simulation is a valuable tool that allows transportation modelers to quantify the impact of different strategies and policies in an unprecedented level of detail. Of course, there are significant caveats in the development of traffic simulation models. If the basic requirements (that is, reasonable data, reliable calibration, and validation, etc.) are not performed, there are

Traffic Simulation

Transportation planning and management is a very complex field that needs to consider a large number

considerable dangers of creating unrealistic models. Current traffic simulation models offer very powerful graphical user interfaces (often offering three-dimensional photorealistic rendering) that make challenging these results very hard.

A successful simulation project comprises three main components: (1) a traffic simulation model, (2) adequate suitable data, and (3) a proper calibration and validation of the model, prior to its application, to ensure that its output matches the real world.

In order to meet the broad needs for traffic simulation, a wide range of traffic simulation models with different properties and characteristics have been developed over the last several decades. Traffic simulation models can be classified according to multiple dimensions, such as level of granularity or fidelity with which they attempt to model traffic. Choosing the appropriate model is a fundamental decision for the success of any simulation project. Often, modelers tend to know a tool well and use it for all tasks, irrespective of its suitability, but, ideally, one should aim to use the right (level of) tool for each task.

Classification of Traffic Simulation Models

Microscopic traffic simulators (for example, AIM-SUN, CORSIM, DRACULA, MITSIMLab, Paramics, TransModeler, VISSIM) entail detailed models of driver behavior, comprising car following, gap-acceptance, lane changing, and other disaggregate behavioral models. These models operate at the individual driver level and utilize a large number of parameters. The internal clock of such models often operates at the level of a fraction of a second, meaning that decisions about the behavior of the travelers and the movement of the vehicles may take place several times per second.

Microscopic traffic simulation allows for a much higher resolution and detail in modeling (in comparison to mesoscopic and macroscopic models), and, as such, it may provide more accurate results. Naturally, this level of detail comes at a computational cost. In earlier years, this meant that microscopic traffic simulation could only be used for limited networks. However, recent advances in computing (for example, hardware developments, parallel computing, and more efficient algorithms) have made the use of microscopic simulation practical even for real-time or near-real-time applications.

Lower resolution (macroscopic or mesoscopic) simulation models usually represent traffic

dynamics in a more aggregate way and may update the vehicle position and characteristics every few seconds. Macroscopic models are well established and mature, because they have been used for several decades already. Computationally, they offer considerable advantages, and therefore they can be used to evaluate large numbers of scenarios or very large networks. Examples of macroscopic models include SATURN and METANET.

Mesoscopic traffic simulation models represent individual vehicles and advance along links consisting of a “moving” part and a “queuing” part of each link. Vehicles move in the moving part according to a speed, which depends on the prevailing conditions, usually density. Vehicles that are queuing at the downstream end of the link are advanced based on the output capacity of the segment.

Microscopic and macroscopic traffic models monopolized the traffic simulation scene for a couple of decades, until the early 1990s, when mesoscopic simulation came to prominence. The idea of mesoscopic simulation is that each vehicle is still simulated independently but, whenever possible, at a lower level of detail. For example, when vehicles are moving in an uncongested freeway, it is not necessary to track the individual lane that they are following. However, when they reach a signalized intersection they need to be assigned to lanes, so that, for example, vehicles making a right turn do not queue and block vehicles moving straight.

Emerging traffic estimation and prediction (or dynamic traffic assignment, DTA) systems, used in real-time applications for traffic estimation and prediction, are simulation-based and use mesoscopic simulation models to capture traffic dynamics (for example, academic systems such as DynaMIT, DYNASMART, DynusT, as well as commercial products such as Dynameq). Table 1 presents some of the comparative advantages and disadvantages of each of the above types of models.

Naturally, the great interest in the field of traffic simulation means that other types of traffic simulation models have also been developed that do not necessarily fall under these categories. For example, hybrid models attempt to combine the benefits of microscopic models (high accuracy) and mesoscopic/macroscopic models (low computational complexity). To achieve this, hybrid models typically operate at a more aggregate level but allow the modeling of specific areas of interest at

the microscopic level. Another field of interest is nanosimulation models, which, as their name suggests, operate at even higher levels of detail (for example, modeling driver cognition, perception, decision making, and errors in greater detail).

Calibration of Traffic Simulation Models

Traffic simulation models include a number of parameters and input data that must be calibrated to match field observations. Calibration methodologies may depend on the type of data that are considered: aggregate versus disaggregate. Disaggregate data include detailed data on the driver behavior, such as trajectory data, while aggregate data include flow counts or speeds, which are the manifestation of the behavior of multiple drivers. Disaggregate data can be used to calibrate individual models, while aggregate data can be used to calibrate the entire traffic simulator at the same time.

Another distinction is sequential versus simultaneous calibration. In sequential calibration, each model or time period may be calculated independently, while in simultaneous calibration, all models and time intervals are calculated concurrently. Sequential calibration is more practical because it corresponds to a smaller problem, with fewer parameters and fewer data to consider, whereas simultaneous estimation offers more efficient use of data, better capturing the interactions between models and time periods.

For operational, real-time traffic simulation models, calibration can be either off-line or on-line. Off-line calibration aims to develop a historical database that supports the simulation model's capacity to match average or expected traffic conditions as captured by (archived) sensor data. While the output of this process is expected to perform adequately in off-line studies, such as the evaluation of alternative traffic management strategies, daily traffic conditions are affected by a number of factors, including incidents and weather conditions.

The off-line, "average," parameters must therefore be updated dynamically to reflect the variability of traffic conditions around their expected values. The accuracy and predictive power of the traffic simulation models may thus be significantly enhanced by re-calibrating off-line parameter estimates using real-time data. The information encapsulated in the historical database (generated

off-line) can be incorporated into this online process as a priori estimates.

While off-line and online calibration have similar objectives, their formulation and solution approaches differ significantly. Off-line calibration is a global optimization step aiming to determine the mean values of the parameters and inputs, while on-line calibration adjusts the off-line values to reflect prevailing conditions. Data from prior days may be available for off-line calibration, while online calibration will generally use smaller amounts of recent, real-time data. Further, off-line calibration has no explicit computational constraints, while online calibration must be faster than real-time. Finally, off-line calibration must estimate all traffic simulation inputs and parameters, while online calibration could focus on a subset of critical parameters.

Validation of Traffic Simulation Models

The final step of a calibration process is the validation, which ensures that the calibration has been properly completed and caveats such as overfitting have been avoided. This step is as essential as the calibration itself, because it also provides a good approximation of the final quality that can be expected from the study at hand. By running the model on a data set not used for the calibration of the parameters, the modeler obtains results for the calibration targets identified during that step and even for their statistical properties.

A large number of indicators are available for the assessment of calibration and validation efforts. Each of these has different strengths and limitations, and the question of which one to use arises very often in practice. The answer to this question is usually complex and may depend on a number of aspects related to the problem at hand, the available data (and their characteristics), and many other parameters. Usually, a reasonable approach is to consider multiple indicators, thus elucidating more aspects of the model at hand and providing a more complete assessment of its performance.

The importance of choosing the appropriate indicators is key in being able to assess the performance of a model. In general, it is difficult to distinguish between "good" and "bad" indicators. However, it is useful to consider the relative advantages and disadvantages of each of them.

The purpose of using multiple statistics is that they can capture different aspects of the obtained

results. The normalized root mean square error (RMSN) and root mean square percent error (RMSPE) quantify the overall error of the calibration. These measures penalize large errors at a higher rate than small errors.

The root mean-square error (RMSE) is a measure of the deviation of a simulated variable from its actual path. The normalized mean error (MEN)

measures the mean normalized difference between simulated and observed values. The mean percent error (MPE) statistic indicates the existence of systematic under- or overestimation in the simulated measurements. Percent error measures are often preferred to their absolute error counterparts because they provide information on the magnitude of the errors relative to the average measurement.

Table 1 Advantages and disadvantages of classes of traffic simulation models

	Advantages	Disadvantages
Microscopic	• More detailed/accurate than mesoscopic/macroscopic • Ability to explicitly model details such as traffic signal strategies, road geometry • Modern microsimulators have graduated from turning-fraction type approaches to OD/path-based modeling	• Computationally expensive • More and more detailed data required • Longer time to develop, calibrate and validate model • Calibration effort is very demanding • Microscopic detail may not be necessary for online applications and contingency planning • Even though micro simulators are getting faster, mesoscopic models would always allow larger networks to be simulated, more scenarios to be modeled, longer prediction horizons
Mesoscopic	• Practical compromise between micro and macro • Combination of aggregate and disaggregate models • Actively researched, especially in the context of real-time forecasts and generation of contingency plans • Allows for longer prediction horizons than microscopic simulation (up to one to two hours)	• Not many practical, large-scale, online applications completed (however, many research/evaluation studies have been undertaken, and several are under way)
Macroscopic	• Computationally very efficient • Mature, widely deployed technology • Can be used to quickly evaluate large number of contingency plans, thus filtering available alternatives to a handful that can then be evaluated in more detail (by another system)	• Dated technology • Not very extensible without moving to mesoscopic/microscopic solutions • Mostly limited in practice to planning/off-line applications

Traffic Simulation Applications

Traffic simulation has a very wide range of applications, ranging from the off-line/planning level to online/dynamic level horizons, and from short-term to longer-term applications.

Short-term forecasting (usually up to one hour into the future) may be useful for traffic management applications, while long-term forecasting (usually up to 15 to 20 years) is usually used for infrastructure planning. Clearly, the objectives of the two applications are very different, which is reflected in the data required for each application. Microscopic simulation offers the level of detail to capture the dynamics of most short-term applications, while mesoscopic (or macroscopic) models are used for the longer-term applications because they often involve larger study areas and thus are more computationally intensive. However, recent advances in computing and algorithmic developments are starting to allow microscopic models to be used in this context as well.

The increasing demand for mobility has led to congestion in multiple modes and infrastructures, but developing new infrastructure is often not feasible or cost-effective. As a result, efforts to resolve the issue are often targeted toward demand management. Traffic simulation applications in this domain focus on the user behavior (especially the response of users to information). In this case, microscopic and mesoscopic models are most commonly used.

Microscopic traffic simulation models support very detailed analysis and modeling of transportation infrastructure, traveler information, and traffic control. Therefore, they can be used as a tool for geometric design and sizing of special infrastructure elements, such as toll plazas, bridges, tunnels, and work zones. Furthermore, traffic simulation can be used to develop and evaluate effective strategies for responding to special events and emergencies in a way that minimizes their adverse effects.

Advantages and Disadvantages

Setting up a traffic simulation model requires a lot of effort and resources, which often raises the question of their popularity. There are many views on this question, but one key answer is that traffic simulation offers a practical way to study the interactions of many different phenomena in very complex problems. Furthermore, traffic simulation offers a practical way to evaluate a large number of

alternatives at reasonably low effort and cost (after the initial cost of developing the simulation model).

An important feature of traffic simulation is that it allows the detailed assessment and evaluation of infrastructure or management schemes that have not yet been implemented, thus providing insight into their expected future performance. Based on this information, it is possible to refine and prioritize the considered alternatives.

Traffic simulation also provides a practical tool that can be used to perform sensitivity analysis on the expected impacts and benefits of considered measures and initiatives, thus providing a realistic envelope of expected conditions. Based on the results of such an analysis, it is possible to proactively manage the range of outcomes of a project and thus be prepared to deal with any contingencies.

The disadvantages of traffic simulation include the high cost of developing the models, acquiring the necessary data, and calibrating the models to replicate the prevailing conditions, and, possibly, the high computational runtime. Developing a realistic model for a reasonably sized network (for example, a city) can take several months, assuming a knowledgeable team of modelers and adequate data. Similarly, once the model is ready, it may take one or more hours to run it for a single simulation (in the case of more detailed models).

Caveats

Traffic simulation is a very attractive option for transportation modelers and decision makers alike, because it provides a rigorous tool that can be used to support decision making. However, there are many situations that can undermine the use of traffic simulation.

One usual problem is the lack of clear goals at the start of the traffic simulation project implementation. Another common issue is the choice of an inappropriate level of detail (either too aggregated or too detailed). The problem of choosing an aggregate model where more detail is needed is obvious. However, the opposite can also be a problem, such as when a too-detailed model is chosen for an application that could be served by a more aggregate model. Although the development of the more detailed model requires additional resources, the introduction of a higher level of detail (and thus uncertainty) that may not be directly relevant to

the problem at hand might dilute the impact of the modeled phenomenon.
